METALLURGICAL AND CHEMICAL ENGINEERING

The Incorporation of
ELECTROCHEMICAL AND METALLURGICAL INDUSTRY
and IRON AND STEEL MAGAZINE

PUBLISHED MONTHLY

VOLUME IX

From January to December 1911

436834
3. 7. 45

NEW YORK:
ELECTROCHEMICAL PUBLISHING CO.

INDEX TO VOLUME IX

GENERAL ALPHABETICAL INDEX

*Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest). Illustrated articles are indicated by *.*

A

ABADY, Jacques 683
Abbe Engineering Co 332
Abbe, Paul O 676
Abrasives, Alumina, magnesia, etc. Allen, (P.) 666
Absorption of hydrochloric acid and other gases. Kingsbury *611
Acetylene explosion *476
Acids, Sulphuric, nitric, and mixed. Census report 680
Acid fan, Heinz-Skinner *674
Aero Pulverizer Co 617

AGITATOR:

——Air-lift. Hills. (P.) 423
——Allen. (S.) 425
——and filter in cyanidation. Hendryx .. *82
——Pulp. Paterson. (P.) 661
——Sicka. (P.) *109
Air-compressor for handling acids *161
Air desiccation by calcium chloride. Daubine and Ray *343
Air furnaces. Oil as fuel. Best *312
Air. Saltpeter. See Nitrogen. Atmospheric fixation.
Akin, A. D 478
Alaska 6
Aldrich, W. H 116
Alkali. Manufacture of ammonia alkali in England. Mason 81
Alkali-proof Portland cement *133

ALLOYS:

——Aluminium alloys..85, 107, 219, 511, 663
——Brass and bronze.....216, 228, 315, 321, 363, 403, 475, 516
——Calcium-copper. Franke (P.) 325
——Casting alloys 332
——Cerium. Hirsch 543
——Conductivity and constitution 603
——Copper 151, 155, 515, 603
——Corrosion by salt water 152
——Corrosion of brass. Bruhl 516
——Duralumin 295
——Electric conductivity and constitution. Guertler 517
——Electrolytic refining. Betts. (P.) 6
——Gold and silver. Parting and refining. Kern *443
——Iron. Electric resistivity. Burgess and Aston 539
——Iron-manganese. Arnold 598
——Lining alloys 473
——Magnesium-zinc alloy. Rubel. (P.).. 156
——Melting point and alloying capacity. Goldschmidt 348
——Nickel-titanium. (R.) 663
——Non-ferrous alloys for high-pressure castings 63
——Pyrophoric 53, 424, 543, 663
——Reduction. Boericke. (P.) 424
——Review of possibilities. Whitney 316
——Scrap melting furnace. Barnes 315
——Sodium and potassium. Electric properties. Northrup 538
——Titanium. Huffard. (P.) 377
Alumina abrasives and refractories. Additions of magnesia, boric oxide, beryllia. Allen. (P.) 666

ALUMINIUM:

——Alloys. Analysis. Smith 85
——Alloys and impurities. (S.) 107
——Alloy. Claessen. (P.) 523
——Alloys manufacture. Mellen. (P.).. 219
——Alloys with zinc. Rosenheim and Archbutt 516
——Aluminum bronze. Durville. (P.).. 663
——Aluminium nitride production. Serpek. (P.) 523
——Electric reduction from sulphides. Keoch. (P.) 523
——Foundry economics. Barnes 315
——Manufacture at British Aluminium Co.'s works. Clacher 146
——Production in laboratory. Richardson 269
——Soldering. Dandelin. (P.) 325
Alundum refractories *225, *476
——Saunders *257
Amalgam barrels. Explosion. Dowling. (S.) 220
Amalgamation and cyanidation of silver ore in Mexico. Brodie. (S.)... 105
Amalgamation. Electrolytic. Atkins. (D.). 618
——Carey *260
Amalgamation of gold in banket ore. Dowling *322
Amalgamation practice on the Rand. Thomas. (S.) 519
Amalgamation. Wiswell. (D.) 618
American Chemical Society. Indianapolis meeting 338
American Chemical Society. Minnesota meeting 62
American Electrochemical Society, 8, 31, 122, 170, 231, 434, 477, 479, 626
——New York meeting. Report *255
——Toronto meeting. Report *524
American Foundrymen's Convention in Pittsburgh 250, 287, 311
American Grondal Co 332
American Institute of Chemical Engineers 122, 290, 482, 622
——Chicago meeting 386
——New York meeting 49
American Institute of Mining Engineers. San Francisco meeting *564
American Mining Congress.....164, 237, 483
American Museum of Safety 57
American Platinum Works 682
American Rolling Mill Co 114
American Smelting & Refining Co 436
American Vanadium Co 332, 477
American Vanadium Facts 195
Ammonia alkali. Manufacture in England. Mason 81
Anaconda smoke suit 123, 432

ANALYSIS:

——Aluminium alloys. Smith 85
——and sampling of gases. Methods of U. S. Steel Corporation... *302, 356
——Automatic gas analysis for boiler house and chemical works control. Simmance and Abady *327
——Arsenic and antimony in anode and cathode copper. Kern and Wen.. *365
——Brit. Nat. Phys. Laboratory 299
——Bureau of Standards analyzed samples 112
——Chromium in chrome-iron ore 515
——Chromium in Chrome-Tungsten Steel. 217
——Ferrohoron. Davis 459
——Gauze electrode for rapid analysis. Benner *141
——Gold assays in the field. Austin. (S.) 520
——Gold and silver in copper. Kern and Heimrod 496
——Grading analyses 187
——Litmus solution 217
——Manganese in steel in presence of chromium and tungsten. Watters 244
——Manganese bronze. Huber 403
——Matte assay. Wilmoth. (S.) 280
——Methane in producer gas and water gas. Worrell *576
——Phosphoric acid. Martin 64
——Portable assay outfit. Bradford. (S.) 155
——Positive rays and chemical analysis. J. J. Thomson *208
——Rotating anode *477
——Separation of iron, aluminium, and chromium 217
——Silver-bearing ore assay. Keyes and Riddell. (S.) 467
——Small lime with much magnesia.... 217
——Sulphur in brass and bronze 217
——Sulphur in coal gas. Blair 321
——Sulphur in ore 677
——Tin ore. Morgan. (S.) 426
——Total carbon in iron, steel, and ferro-alloys. Quenean *441
——Tungsten ore. Watts 414
——Tungsten. Volumetric determination. 321
——Vanadium. Bleecker 209
——Wulfenite ores. Davis 458
Annealing copper. Johnson *87
Annealing. Malleable iron. Putnam *315
Anode. Rotating *477
Anode sludge of electrolytic refineries. Treatment. Kern *417
Ansonia Brass & Copper Co 475
Antimony. Distillation process. Fink. (P.) 667
Antimony and gold ore. Electrolytic treatment. Schreiber and Knutsen. (D.) 560
Antimony determination in anode and cathode copper. Kern and Wen. *365
Arbuckle process of ore treatment 141
Argall, Philip 618
Arizona 483
Arizona Copper Co 114, 115, 182, 442
Arsenic. Distillation process. Fink. (P.) 667
——antimony alloy. Electrolytic treatment. Betts. (P.) *378
——determination in anode and cathode copper. Kern and Wen *365
——in copper refining. Wen...318, 365, 536
——from ores. Peck. (P.) 523
Asbestos. Fibrous 417, 476, 683
Ashland Fire Brick Co 332

B

BABBITT 473
Baekeland, L. H 57
Bain, H. F 430
Bakelite 114
Balance, Voland 683
Balance sheet, Chemical. Beckman 194
Balbach, Edward 165
Balbach-Thum parting cell *445
Ball, H. S 683
Basic slag. Phosphates in 655
Bastian, L. D 559
Battery posts. Securing 475
Bayonne Casting Co 617
Benner, R. C 559
Bettles, Alfred J 478
Bicarbonating process 594
Blake, L. I 285

BLAST FURNACE:

——Bosh construction. Zippler. (P.).... 281
——Charging apparatus. McKennan. (P.) *108
——copper. Austin 41
——Copper blast furnace tops. Emmons. (S.) 220
——Gas. Sampling and analysis. Methods of U. S. Steel Corporation.. 356
——Hydrocarbon blast furnace for lead and copper. Nesmith. (P.)... *470
——Hydrogen in blast-furnace gas. Wysor and Brown 67
——Oxygen for blast *31, 174, 238
——Utilization of wastes. Hagar 407
Blast roasting. Sintering fine iron-bearing materials 431
Bleaching cotton. W. S. Williams 247
Bleaching oil with Fuller's earth. Wesson. (S.) 51
Bleecker, W. F 285
Boiler firing with producer gas 673
Boiler, Fitzgibbon. Alexander. (S.).... 52
Bone, A. J 116

BOOK REVIEWS:

——Bain. More recent cyanide practice. 58
——Barr. Testing for metallurgical processes 117
——Baskerville and Curtman. Qualitative chemical analysis 334
——Bayley. Elementary crystallography. 117
——Bowles. Tables for determination of common rocks 117
——Buchanan. Practical alloying 334
——Cameron. Soil solution 684
——Desch. Metallography 117
——Freundlich. Kapillar-chemie 230
——Greco. Elementi di metallurgia..... 117
——Hart. Welding 166
——Hendricks commercial register of the United States for buyers and sellers 618
——Hinds. Qualitative chemical analysis 334
——Kahlenberg. Outlines of chemistry. 118
——Louis. Metallurgy of tin 618
——Mennicke. Metallurgie des Wolframs 684
——Mennicke. Metallurgie des Zinnes.. 430
——The M. C. C. periodic chart of the elements 118
——Olsen. Van Nostrand's chemical annual 58

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. IX. New York, January, 1911 No. 1.

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

239 West 39th Street, New York.

Pittsburgh Office, 201 Oliver Building.
Western Office, 1510 Court Place, Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

J. W. Richards, Ph.D., President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.
Telephone Call: 4700 Bryant.

E. F. Roeber, Ph.D., Editor.
H. C. Parmelee, Western Editor.

Yearly subscription price for United States, Mexico and United States dependencies, $2.00; for all other countries, $2.50 (European exchange, 10 shillings, 10 marks, 12.50 francs).

Copyright, 1911, by the Electrochemical Publishing Company.

Entered as Second-Class Matter at the Post Office at New York, N. Y., under the Act of Congress, March 3, 1879

New York, January, 1911.

The Position of Electrochemistry in the Chemical and Metallurgical Industries.

When the story of the industrial evolution of the United States will be written by some future historian who must be both a philosopher and an engineer, one of his brightest chapters will deal with the glorious history of electrochemistry at Niagara Falls. On Aug. 26, 1895, the Niagara works of the Pittsburgh Reduction Company started the manufacture of aluminium. On Oct. 19 of the same year the current was turned on at the works of the Carborundum Company. In quick succession came calcium carbide, artificial graphite, phosphorus, ferro-alloys, made in the electric furnace, and metallic sodium, caustic and chlorine, chlorates, made by electrolysis. In the span of 15 years these pioneer electrochemical industries and others that followed have become so firmly established in the industrial world that their products are well-nigh indispensable in present civilization. We have forgotten that not so long ago aluminium, carborundum, calcium carbide were unknown. The revolutionary features of the early inventions are gone. What remains are splendidly flourishing industries developing along logical lines into ever-extending fields of usefulness. We have almost learned to look at the pioneer Niagara works as the older generation of electrochemical industries. This is said in a spirit of filial pride. For if Germany may be justly proud of having nursed and raised the coal-tar chemical industries, the United States can claim applied electrochemistry as distinctly American. The bulk of these electrochemical industries was not imported, it was made, born, nursed and raised at Niagara by such pioneers as Acheson and Hall and by those who worked with them or followed them. So far they represent the most distinctly American phase in the history of applied chemistry. But from a broader viewpoint—that of the conservation of our natural resources about which many talk so much and think so little—electrochemists have done more at Niagara. They have made at least a start in modifying popular conception of beauty in the direction expressed in Lord Kelvin's remark that "the great cataract will never be beautiful until it has ceased to be such an awful and unlovely example of waste." There is dramatic beauty in the kinetic energy of the Falls, but there must be and will be as much beauty in the transformation of this kinetic energy into the potential energy of innumerable electrochemical products for distribution for the welfare of mankind all over the land.

Aside from these specifically electrochemical industries, electrochemical methods are exerting an ever-increasing and broadening influence in general metallurgical and chemical industries. Of course, there is nothing essentially new in this development. Electroplating is one of the oldest electrical arts, and electrolytic copper refining, carried out on a large scale since the start of the Balbach refinery in 1883, has now assumed enormous proportions and has become indispensable in modern copper metallurgy, both on account of the necessity of pro-

ducing very pure copper for electrical work and of the easy recovery of the precious metals. But, after all, these were applications of electrochemistry to isolated though important problems. The more general tendency towards electrochemical methods did not manifest itself until the success of the aluminum, carborundum, calcium carbide and graphite industries had attracted general attention. To some extent it is the relation of effect and cause. But that is a somewhat superficial view. It cannot be merely incidental that practically simultaneously theoretical electrochemistry came into existence by the foundation of the electrolytic dissociation theory through physicists rather than chemists in Germany and the large electrochemical industries were founded through American engineers rather than chemists. Clearly the scientific as well as the industrial atmosphere was supersaturated and those two nuclei were the first to form and to grow crystallike. Naturally, others followed quickly. So there came into existence the tendency to try and apply electrochemical methods to all possible problems of general chemical and metallurgical engineering. The immense possibilities of industrial electrochemistry became apparent as well as its limitations. Electrolytic refining was extended to silver, gold, and lead. In gold metallurgy there are now on one hand the various attempts to improve the efficiency of the amalgamating plate by making it a cathode in an electrolytic cell and, on the other hand, the proposition to substitute cyanamide with electrolysis for cyanide. In zinc there is great activity on one hand in the development of electric furnace processes, and, on the other, in dry chlorination and electrolysis. In the iron and steel industry the peculiar local conditions of California, Canada, Sweden and Norway have encouraged large-scale and well designed tests of reducing pig iron in the electric furnace; but the largest and most important industrial development is the appearance of the electric furnace for steel melting and refining on a commercial scale. In chemistry the electrochemical fixation of atmospheric nitrogen in form of nitric acid and nitrates or in form of calcium cyanamide affects the explosive and fertilizer industries. Thus there is rapid evolution. The fact that it is still rapid in many lines proves that equilibrium has not been reached, that we are still far from finality. But this evolution is concentrated on distinct promising problems and proceeds along distinct logical lines. The most characteristic feature is perhaps the broadening of the viewpoint from electrochemistry to physical chemistry. Thus in the fixation of atmospheric nitrogen we have in cyanamide manufacture the problem of separating nitrogen from oxygen by cold, in Haber's ammonia synthesis the increase of reaction velocity by certain catalysers with unusually high atmospheric pressures. Thus this evolution has had an immensely broadening effect on all the workers. The rise of the chemist above the pure analyst, the emancipation of the chemical engineer, the dissociation of the metallurgical from the mining engineer are logical concomitant phenomena; and chemical and metallurgical engineering becomes essentially applied physical chemistry.

The Metal Markets in Retrospect and Prospect

It can be well said that just at present the metal markets are slowly recovering from a neurasthenic condition. Now, excessive introspection is equally bad for anybody in such a state. It is usually better to work than to think about the "whys" and "wherefores." Yet, "if we must philosophize, we must philosophize, and if we must not philosophize we must still philosophize." Accordingly, with the New Year's chimes of Trinity Church still ringing in our ears it may not be amiss to look over the metal markets of the past year and also to see what are the signs for the future. Considering the metallurgical industry from the standpoint of a few years back we see that the great increase in production and its concomitant consumption starting in 1898 continued with more or less momentum for 10 years, until the panic of 1907 and the industrial depression that followed it put effectively the brakes on the movement of expansion; that subsequent to this the metal industries recovered very quickly in tone, until the summer of last year, when a second retardation was felt, followed now by a period of liquidation, quiescence and perplexity.

The reasons for this are many—for, indeed, in what dominion of human knowledge is there not a multiplicity of causes? But mainly and chiefly the present unpleasant condition can be attributed to the fact that we recovered entirely too quickly from the period of retrenchment and liquidation of 1907, starting too soon on an error of extravagance and inflation. Secondarily, we have as minor causes the fear of more legislation that is hostile in intent to capital and the uncertainty about the judicial inquiries into the commercial ethics of the trust question and the expounding by the Supreme Court of the eternal verities of the law to changed conditions. Naturally, this has induced a spirit of unrest in the investing public. Direct in its application to the metal markets is the refusal of the railroads to buy in their usual quantities. In quite a human way the railroads do not care to purchase unless they are allowed to raise freight and passenger rates as compensation for the increased wages given their employees. Furthermore, we have the everywhere-present demands of the wage-earning classes for continual increase of pay. In one intense aspect, we have a strong inhibiting cause. That is the high price and uncertain market for cotton, the staple which means so much to us as an exporting nation and so much more to us as a manufacturing nation. All the above enumerated causes act as mental depressants on all industry and though exaggerated in point of fact are none the less potent in their effect on the minds of business men. In short, things are unsettled and no sure foundation for such an expanding industry, such as normally is the metal and chemical industry, can be made until things are more definite.

Let us consider briefly in this light the several special markets aside from the iron and steel market, which is discussed in another column. Like our steel men the copper producers have had also their pleasing prandial conferences. Possibly the dire straits of some of these convivial spirits has moved to compassion the industry and helped to hold up the price of the red metal. At any rate, production has been curtailed. The electrification of the railroads is proceeding much slower than had been anticipated by the large copper interests. The development of the large porphyry ore beds of Utah, Nevada, New Mexico and Arizona has led to the existence of mines that can make copper at an extremely low price. The exactitude with which the cost of development and plant and the cost of producing the metal can be prognosticated has attracted capital rapidly to this kind of mines. The net result is a largely increased and still increasing productive capacity which can sell copper at a profit at 10 cents a pound.

This has effected an over-production and we have seen the price of copper held down to an average of less than 13 cents with a large surplus built up in years of industrial depression. We are not so bearish on the copper industry, especially as enforced economies are reducing the production costs of the older producers. Besides, the low price has caused the use of copper in many new minor ways in the building trade. In this age of electrical development there cannot long be too much copper. It is interesting to note that the high prices of copper in 1906 and in the first half of 1907, due quite largely to the short-sighted policy of the producers in exaggerating the runaway market for the metal, is a cause of this overproduction. For this high price stimulated the promotion and development of these large low-cost producers that now threaten the market. "As ye sow, so shall ye reap." In the steel industry a broad policy has certainly been pursued, even if cynical Wall Street sees nothing but glittering generalities in the pleasant dinners of the gentlemen directing the policy of the different steel concerns. If a similarly broad policy like that observed in the steel industry had been pursued with copper things would have been better for the producer to-day. It is not unnatural to expect in the course of time the consolidation of the several larger concerns into one concern or trust that will control 50 per cent of total production. This will probably be better than the proposed large central selling agency. But the psychological moment for the birth of the copper trust has hardly yet arrived. A logical inference is that the definite character of the ore reserves of the porphyries will lend the stability to the concern that is needed to enlist the support of the banking interests. It would almost seem that the conditions now are exactly analogous to those existing 11 years ago when the great iron ore beds of the Mesaba range assumed an increasing industrial importance.

Turning to the zinc business, we find that it has only been satisfactory to the mining end of the business. The market for spelter has fluctuated between fairly high limits, but the smelting margin has been so low that money alone was made by the smelting concerns possessing great power and hold on the market. The final decease of Iola as a smelting center after years of a prolonged lingering illness is expected this winter. The tendency is to build new spelter plants in the Illinois coal fields. The sensational finds of carbonate ore in Leadville and the reduction to a commercial basis of the Huff electrostatic separator will, among other factors, ease in the ensuing year the position of the smelters. While it is so cheap to build competitive plants, and small plants can be so efficiently operated in the zinc industry, the idea of a zinc trust is chimerical.

In the lead market restricted production of ore, due to the approaching exhaustion of certain large mines, has unquestionably brought the market into a position much brighter from the viewpoint of the producer. Statistical evidence is wanting, but it is probable that the price for 1911 will average higher than the price for 1910.

Silver has been absorbed by the Far East to quite an extent. There has been of late a generally healthy tone to the silver market and a continuation of this can be legitimately anticipated. It is the one metal save gold—for which, as many an alluring gold mine prospectus has told us, Uncle Sam is an unlimited customer—about which there is little perplexity.

In all the other markets the chief feature is the perplexity and doubt on the part of the consuming public. Could an intelligent despot by his fiat take the stand and say "all metals will be sold as per a certain schedule for a period of five years," and could he make the statement with means to back it up: "I will buy copper in any amount for 13⅞ cents and I will sell copper in any amount at 14 cents," consumption would increase at once. But fortunately no one man possesses the power or the means or the intelligence needed to be such a despot. And the only cause for the perplexed human consumer is to pursue a careful course.

In conclusion, we might say that metals are produced now more efficiently than ever before and that each year civilization finds new uses for them. This is a general encouraging feature. In particular a bright feature is that our crops are unrivaled in size and prices lower. Of course, we will always have social agitation, for the extravagance of the foolish must always be expected and a certain class of people will be discontented and agitate for their alleged rights. Questions that perplex the metal markets to-day will not perplex them next year. Then there will be a new set of troubles. We do not now think that the metal industry is in such a bad way. For when things are bad, they are never really as bad as people imagine. Just one thing is certain. Those in the metal business who work hard and intelligently at their own affairs will have little time for morbid introspection and what philosophizing they do will be pleasant.

Iron and Steel in 1910.

The story of what occurred in 1910 in the iron and steel trade is soon told. Why it occurred is, as our friend Kipling would tell us, "another story," and, we might add, a much longer story, if, indeed, it can be told at all. The year opened with the United States producing at the rate of about 31,000,000 tons of pig iron a year, and finished products in proportion. Three years, 1906, 1907 and 1909, had shown a production between 25,000,000 tons and 26,000,000 tons, but no calendar year had crossed the 26,000,000-ton mark. From April, 1909, to February, 1910, there was a steady gain in production. After February production declined, somewhat rapidly during the second quarter, very slowly during the third quarter, and very rapidly during the fourth, so that the rate at the end of the year was not much above 20,000,000 tons, in terms of pig iron.

Prices of pig iron declined almost steadily, but very slowly, through the year. Prices of finished steel products declined rather easily from early in January until the forepart of August, total declines in finished products outside of rails and tin plates averaging not far from $3 a ton. The prices of rails and tin plates did not decline during the year. In August the nominal prices were shaded in some cases, whereas at the close of the year the same nominal prices prevailed and were not being shaded. The circumstantial evidence is that a "controlled market" came into being.

The steel mills entered the year with a very large, though not unprecedented, volume of business on their books. Uniformly shipments exceeded new bookings, and month by month the accumulation decreased until by the close of the year the

mills were shipping almost wholly on current orders. A natural sequence to the continued expiration of old contracts was an increase, beginning in August, in new bookings, but as the new buyers thus appearing were merely those whose contracts had expired the actual demand for material did not increase thereby

We estimate the production of pig iron in 1910 at 27,150,000 ± 150,000 gross tons, comparing with previous years as follows:

1902, 17,821,307	1906, 25,307,191
1903, 18,009,252	1907, 25,781,361
1904, 16,497,033	1908, 15,936,018
1905, 22,992,380	1909, 25,795,471

1910, 27,150,000 ± 150,000.

The calendar year is altogether too long a period to show the real vicissitudes of pig iron production. While neither 1906 nor 1907 showed as much as 26,000,000 tons of pig iron produced, the twelvemonth ended June 30, 1907, showed 26,200,000 tons. The calendar year 1908 fell fairly well in the trough of reduced production, but 1909 and 1910 fell one upon the ascent and the other upon the descent of the curve. Maximum production was in February, 1910, and the twelvemonth of greatest production was that ending July 31, 1910, it covering a production of no less than 29,800,000 tons.

The explanation of why a year opening with such promise broke previous production records and yet constituted on the whole a bitter disappointment would be written differently by different observers, according to their viewpoint. One, full of old time ideas of the importance of railroad buying, would attribute the recession in buying to the refusal of the government to allow the railroads to advance their freight rates, at least without the serious consideration of the Interstate Commerce Commission, which is still in progress. It was early in April that it became apparent that the rate advances could not be made without a contest, and about that time railroad orders became light Another, accustomed to regard political developments as exerting one of the most serious influences upon business, would cite the change in political sentiment in the country as the cause of the slowing down in the industry A third, irrevocably given to the open-market method of transacting business, would ascribe the reversal in the iron industry to the recently devised system of price control, being responsible, first, for an unhealthy boom after the great price break of February, 1909, following a period of 15 months' price control during a period of slack demand, and, second, for the abstention of buyers in the closing months of 1910 when price control was again in evidence.

Probably all these causes contributed toward making 1910 what it was. In the upward movement in the second half of 1909, after prices had found the lowest level for nine years, producers frankly stated they were advancing prices to choke off buying, but the more they asserted that the more buyers were encouraged to buy, in some cases making contracts for forward delivery, in other cases actually taking out the material and adding to their stocks. To support the position in which the iron and steel industry found itself at the opening of 1910 there was required a general and marked improvement in the general consumptive capacity of the country. This was experienced, perhaps, to a limited extent during the early months of the year, but when railroad buying was largely shut off the industry had to run on its accumulation of railroad orders. The accumulation decreased rapidly toward the close of the year, while the general requirements of the country probably underwent some diminution also.

At the close of the year the paramount question was: Is the liquidation still running its course, or, as the revival a year earlier went too far, has the recession also gone too far? A very few months of the new year will determine, and we think it will determine in favor of the latter alternative. To the close-range view the matter of prices of finished steel products is an element, there being a sentiment widely prevalent among buyers and not absent entirely from the ranks of producers that finished steel prices should be reduced. This we consider a detail which the more vital elements will settle. If business is in position to revive in a marked way, the present system of price control will yield. If there is no hope for radical improvement in any case, or if there is good promise of improvement without price reduction, prices will hold.

Western Steam Coal.

Chemists and engineers long have recognized important differences between Eastern and Western coals. These differences are so marked that methods of proximate analysis devised for Eastern coal are not always suited to Western coal, or at least the results of such analysis on Western coal are not capable of the same interpretation. Again, methods of boiler firing and types of boiler construction which are useful and efficient elsewhere have been found deficient in the West. In many sections of the West the coal available for steam purposes is a lignite containing 40 per cent to 48 per cent fixed carbon, 32 per cent to 37 per cent volatile matter, 5 per cent to 23 per cent moisture and 2 per cent to 14 per cent ash. The calorific value is about 11,000 b.t.u. The high percentage of volatile matter is the distinctive feature of this coal. If consumed under ordinary conditions, this same volatile matter, which contains about 17 per cent of the calorific value, is also the cause of the greatest loss in efficiency, so that even though the coal may have the same calorific value as an Eastern coal it will give much lower efficiency when burned under the same conditions. This is due to the fact that the volatile matter is easily driven off from a freshly fired charge of coal at a temperature low enough to distil it, but not sufficiently high to bring about combustion. The gases thus escape from the zone of action unburned and reduce the efficiency of the operation.

These peculiar conditions have caused Western engineers to devise special furnaces and means of firing, whereby the efficiency of Western coal may be greatly increased over former practice, and made to approximate closely that of the East. A thick fuel bed, mechanical stoking and forced draft, with preheated secondary air, have been found valuable in burning this fuel. This idea has been applied not only to boilers for steam-raising purposes, but also to metallurgical furnaces, such as roasters and reverberatory smelters. Forced draft has been applied in various ways and improvement has been marked in this line. Using steam direct for forcing the draft has consumed about 18 per cent of the steam raised. When using fans driven by steam engines the steam consumption has been reduced to about 12 per cent, while more recent devices embodying small turbines and fans are credited with a consumption of

only 4 per cent to 6 per cent of the steam raised. A difference of opinion exists as to the value of injecting steam with the draft, although this probably refers more to the quantity used and manner of application than to its total elimination. Another interesting phase of the use of Western coal is the improvement which is noted where coal is bought on specification, with a graded schedule of prices for fuel value. One notable instance is that of an institution using slack of a certain specification. As long as little attention was paid to the grade of the coal it was of poor quality and the efficiency of the steam plant was low. As soon, however, as chemical control was instituted, the grade of the fuel promptly rose with corresponding efficiency in the power plant.

National Faults in Manufacturing.

The American people have been styled often by Europeans "a nation of shopkeepers." This remark certainly has a modicum of truth in it. While it is perfectly true that we display at times an intense striving for the immaterial and for the spiritual, yet all of us are more or less of the time quite nimble dollar-chasers. Possibly in our desire for acquiring money we overreach the mark, but we are not the only ones. American visitors in England and continental Europe have remarked on a certain convulsive grasping after the last farthing, centime, or pfennig that suggests that Europeans criticism of our weakness for money is founded on the critics' ability to see the mote in the American eye and to disregard calmly at the same time the Continental beam.

However that may be, concisely stated, Americans are business people and are fond of the business game. Now this tendency is often too intense and the vision focused so closely and so continuously on the intermediate object in view as to make the American business man myopic. A quite prominent manufacturer of special steels was discussing recently an intricate phase of the working of the automobile with a metallurgical engineer in a New York club. The former showed such an intellectual grasp of the broad principles of a business foreign to his own that the latter ventured to ask him whether he was considering the introduction of the electric-steel furnace in one of his plants. Quite to the surprise of the metallurgist this man, broadly intelligent outside of his own field, was only narrowly intelligent in his own field. He confessed never to have heard of the electric-steel furnace as being anything more than a toy. Now, for years this journal has been reciting the potential advantages of electric steel making and also the practical achievements of the several electric-steel furnaces in this country and in Europe. Recently also the general technical press has not been backward in following the lead of METALLURGICAL AND CHEMICAL ENGINEERING. Furthermore, the largest steel company in the world has demonstrated the commercial utility of the electric-steel furnace. And yet this manufacturer of special steels, so keen in looking at the automobile business in a philosophical manner, had centered his mind so closely to the actual carrying out of his operations from day to day that he could not see that his concern would be saved from the ever vexatious labor question by the introduction of the electric-steel furnace. Verily, as the sage remarked, "some people cannot see more than six inches beyond their nose."

Our metallurgical friend had the tact to awaken the manufacturer slowly and also the sagacity to test the sincerity of his remarks. For some people assume an attitude of ignorance in order to gain expert knowledge without paying for it. The steel manufacturer simply had the inability to see the architectonics of his manufacturing structure. He had exaggerated the value of salesmanship (that side of the subject he understood perfectly) and he laid too much stress on the value of practical and resourceful foremen. These details are, of course, well-nigh essential and always exceedingly important. But, but, and but, they are not the sum total of high-class manufacturing.

The three prime elements of successful manufacturing are, first, to have a clear view of the commercial and financial aspects of the situation; secondly, to pay close attention to the practical and engineering sides of the subject; and thirdly, to have ever in mind an imaginative, yet reason-tempered conception of the many possible applications of physics, chemistry, and other pure sciences to the special class of manufacturing on hand. This analysis is but a rough one, just as an analysis of concrete as an aggregate of cement, sand and crushed stone without further chemical or physical determinations is a rough, general analysis. But though rough, we believe it sufficient and practical for pragmatic purposes. It is accordingly only too evident that the American manufacturers exaggerate the importance of the engineering and strictly commercial sides of business affairs.

To attain perfect sanity in an individual a proper balance of the physical and mental and emotional energies is necessary. Without these co-ordinated properly, a departure from the highest normality is made, varying, according to the disharmony of the forces and their magnitude, from everyday folly and extraordinary silliness, till eccentricity, incompetence and finally insanity is reached. Just so in the practical world of business to attain the fullest measure of success there must be a co-ordinated balance of the three different components. The average American manufacturer has overdeveloped two sides and neglected the third side. When he turns to the use of the projected imagination he often shows a queer form of activity as, for instance, the desire to get gold out of seawater, or the willingness of a banker to capitalize an attempt of making silver from lead. Probably his imagination is so seldom used that when it is used it is stimulated to such an extraordinary degree that his otherwise sound judgment is paralyzed.

While American manufacturers do not pay attention enough to the possibilities of applied science, German manufacturers perhaps pay too much attention to pure science. In many large German works a few less doctors of philosophy and a few more hard-headed Yankees would improve things. It is not necessary for us to criticise much the policy of our Teutonic confrères. They have developed their business to meet the actual conditions confronting them. But they do not know all the possibilities of the game any more than do our own manufacturers. Both have characteristic points of weakness. Each country can learn and, we are glad to say, is learning from the other. For there is no tariff on the interchange of ideas. It is grandly true that in the realm of ideas reciprocity expands freely by laws made not by man but by God.

Perkin Medal

At a meeting of the Perkin Medal Committee, consisting of representatives of the Society of Chemical Industry, the American Chemical Society and the American Electrochemical Society, the Perkin medal for the present year was awarded to Mr Chas. M. Hall, of Niagara Falls, for his pioneer work in the aluminium industry

The formal presentation of the Perkin medal to Mr. Hall will be made at the next meeting of the New York Section of the Society of Chemical Industry.

The Western Metallurgical Field

British Columbia.

The investigation of the zinc resources of this province, which began about five years ago, is still being prosecuted by the Dominion government under the direction of Dr. Eugene Haanel, director of the Department of Mines. Experiments are now being conducted at McGill University for the purpose of solving some of the fundamental difficulties in the reduction of low-grade zinc ores by electric methods. When this is accomplished it is proposed to erect an experimental plant at Nelson, where tests will be conducted on a larger scale. Electric smelting is only one of the processes being investigated by the commission having the matter in charge. Ore has been shipped to the university from a number of the properties having zinc ore, and the possibilities of treatment are being thoroughly investigated by the commission, which includes Dr. A. Stansfield and Mr. W. R. Ingalls.

The new Portland Canal district was recently visited by the provincial mineralogist for the purpose of issuing a preliminary official report. As yet there is but one producing property, although a number of owners are prosecuting development work. The Portland Canal Mining Company, of Victoria, has erected a 75-ton concentrator, which is designed to be one unit of a larger mill if the developments warrant. Ore is conveyed by aerial tramway, and concentrated about 4 into 1, with a clean separation and good saving

Alaska.

Sluicing and dredging in the Nome district were brought to a close earlier last year than usual, and as a result of this and other causes the output for 1910 will be from $250,000 to $500,000 less than for 1909. The production from the Seward Peninsula as shown by the Customs Office was about $3,500,000 for 1910, as compared with slightly over $4,000,000 for 1909.

Other conditions contributing to the reduced output were the early closing of the navigation season, a late spring, and the partial exhaustion of some of the pay streaks. Nineteen dredges were in operation during the year, but of this number 16 closed unusually early.

About 10 new dredges were built in the peninsula last season, and these, together with others to be built next year, will make a total of 24, most of which will commence operations as soon as possible next spring.

Mexico.

The recent demonstration against the government has not amounted to as much as United States papers intimated, and personal advices from the southern republic indicate that the revolution has never been serious. In view of the large metallurgical interests controlled by American capital in Mexico, it is gratifying to know that there is no immediate prospect of a disturbance there. There can be no doubt that the growing supremacy of American capital and industry in Mexico is distasteful to a part of the Mexican population. On the other hand, the officials have recognized the value of the foreign element and have encouraged their work by offering favorable concessions.

The Pacific Smelting & Mining Company, a New York concern is laying plans to become a strong custom smelting company in northern Mexico. It has recently purchased a concession for erection and operation of a custom smelter at Mazatlan, Sinaloa. Two other plants are under construction by this company, viz., one each at Fundicion and Guaymas, Sonora, and both will be in operation early this year. With three plants drawing from the mining districts of Sonora, Jalisco, Tepic, Sinaloa and Durango the company will be a strong factor in Mexican metallurgy.

The Cananea Consolidated Copper Company, of Cananea, Sonora, will treat the concentrates produced by the new mill of the Miami Copper Company, Arizona, delivery to begin about January, 1911. Special bin and furnace equipment have been installed to accommodate this increased supply of ore

Nevada.

One of the less prominent districts of Nevada is known as Seven Troughs. Although not so well known as some others, it produces some rich ore and has some mills that are reported to be doing good work. The Seven Troughs Coalition Mines Company has a 10-stamp amalgamation-concentration mill in which the low-grade ore is treated with a good recovery. The tailing loss is expected to be recovered by cyanidation in the future, and tailings are being impounded in anticipation of installing that process.

The most pretentious plant in the district is that of the Darby Ore Reduction Company, at Mazuma. Ten stamps reduce the ore to pulp, which then passes over plates, and later, over Deister concentrating tables. The table tailings are classified into sand and slime by Dorr classifier, the sand being ground in tube mill and amalgamated before joining the slime for cyanide treatment. The latter process is carried out by agitation in tanks and filtration on Oliver continuous filters

One of the newest districts in Nevada is known as Jarbidge, situated in the northern part of the State. The developments have proceeded far enough to warrant one company, the Pavlak, erecting a cyanide mill, which is now under construction. In order to aid the pioneer companies as much as possible the county commissioners have ordered a road built into the camp, making good connections with the Western Pacific Railway at Deeth.

Utah.

The recent report of the Utah Consolidated Company, which showed such marked discrepancies between the supposed and actual state of the property, was a great surprise. It had been generally supposed that, while the Highland Boy mine was not in the promising condition which it once enjoyed, it was, nevertheless, in possession of three to five times the reserve which the last report showed. This opinion was supported not only by the previous reports on the property made less than a year ago, but by the fact that the International smelter was built at Tooele ostensibly relying on the ore from the Utah Consolidated for its main supply. At present it appears that the anticipated ore supply will not be forthcoming, and that another year will see the finish of shipments from the Utah Consolidated to the International.

This has necessitated a campaign for other ore supply, and one of the possibilities mentioned is that the Giroux company will ship to Tooele instead of building its own smelter in Nevada. This would involve an adjustment of freight rates over several railroads, but in view of the difficulty in securing a large copper tonnage under present conditions, shipments might be made even if arrangements were not as good as the best. The Tooele plant is our newest and most complete copper smelter, as has been outlined previously in these columns, and favorable rates would undoubtedly be made rather than have it idle wholly or in part.

In the meantime conditions at the Garfield plant of the American Smelters Securities Company are more flourishing than before, both as to capacity and ore supply. A sixth reverberatory furnace has been built, and the converting capacity has been increased by additional Peirce-Smith basic lined converters. All of the reverberatories and three out of four

blast furnaces are running. These changes have been made necessary by the increased output of the mills of the Utah Copper Company at Garfield, and the combination bids fair to make Garfield the greatest copper concentrating and smelter center in the country.

Experiments looking toward improved zinc concentration at the Daly-Judge mill, at Park City, have been under way for some time. Retreatment of the mill slime on tables is being tested, and in addition to this tests are being made with the MacQuisten tube in an endeavor to improve the quality of the zinc product

Colorado.

The recent completion of the Newhouse tunnel in the Gilpin district, and the connection of the Roosevelt tunnel at Cripple Creek with the El Paso shaft, are regarded as two events which will have an important bearing on the immediate future of Colorado mining and metallurgy. The Newhouse tunnel is 21,968 ft. long, and provides drainage and transportation facilities for a mineralized area which has been very productive and which still contains large quantities of ore suitable for preliminary concentration or final reduction in the mills of the district. The Roosevelt tunnel has been driven about 16,000 ft. and has 14,000 ft. yet to be driven before its objective point is reached. In the latter portion of its course it will effect the drainage of the area which has a common water level and which contains numerous gold-bearing veins. In view of the undoubted efficacy of the cyanide process in the treatment of these ores the completion of the tunnel will undoubtedly open the way for the erection of new mills and the creation of a new metallurgical era for Cripple Creek.

The Non-Ferrous Metal Market.

A general state of depression has pervaded the market for non-ferrous metals, and the feeling regarding the future is divided. Interest in copper is centering about the efforts being made to realize an agreement among the large producers, for it is believed that some plan of co-operation will be necessary for the good of the industry. Prices for all metals have been almost stationary or reduced since our last monthly report.

Copper.—Although the producers are endeavoring to hold the market at the advance which it experienced in November it is apparent that purchasers are not inclined to buy at the high figure, and as a consequence the prices are being shaded for most transactions. Lake copper has been offered freely at 12¾ cents to 12⅞ cents, and electrolytic at 12.5 cents to 12.6 cents.

Lead.—Considerable business has been transacted on contracts, but the market is quiet. New York quotations are 4.5 cents, and St. Louis 4.35 cents to 4.37½ cents.

Tin.—The advance in the foreign market and the apparent control of that market by the bull interests has resulted in a slight advance at home, although the volume of business is light.

December tin was quoted in New York at 38½ cents.

Spelter.—In common with the other metals, spelter has been depressed and has lost its favorable position reported last month. Inquiries for metal are few and competition among the sellers has been keen. Prices have steadily declined from week to week, and the metal is quoted at 5.47½ cents to 5.52½ cents, St. Louis, and 5.62½ cents to 5.67½ cents, New York.

Other Metals.—Aluminium has remained quiet at 22½ cents to 23 cents for No. 1 ingots. Antimony is unchanged at 7 cents to 7⅝ cents for various brands. There is a fair business in quicksilver at $42 per 75-lb. flask at New York and $41.50 at San Francisco.

Camp Bird, Ltd., Ouray, Colo., operated its mill 30 days in September last, treating 6690 tons of ore and recovering 6281 oz. of bullion and approximately 761 tons of concentrates. The monthly report for September shows about $85,703 applicable to profit.

The Iron and Steel Market.

The stagnation which developed in the iron and steel market late in November was intensified in December, and further and sharp reductions in output were made in the steel industry. In the merchant furnace trade some curtailment of output occurred, but obviously not enough to take up the slack, and December witnessed an increase in the accumulation of pig iron stocks which has been practically continuous all year

Following the general meeting of steel manufacturers in New York on Nov. 30, a series of meetings of producers in individual lines occurred, the meetings covering in turn rails, structural shapes, sheets, tin plates, merchant bars and plates. These meetings were held not for the purpose of fostering a definite price agreement, but rather for the purpose of interchanging information and encouraging manufacturers to curtail output.

Many plants closed entirely for the last fortnight in the year, and others closed for the last week. Altogether there has been the greatest holiday slowing down in the industry that has occurred for many years. At the close of 1903 and again at the close of 1907 there was sharp restriction of output, but in those cases the definite movement began in October or earlier, while last month the curtailment was so great, following the very gradual curtailing tendency which had been in evidence, that it partook of the nature of a separate movement.

Prices of finished steel products have been very steady, there being less shading of openly recognized prices, as a rule, than in October or November. The precise cause of the steadiness cannot be stated absolutely, it being apparently the resultant of the meetings which had been held in the trade and the complete indifference of buyers, which removed quite largely the temptation to invite business by cutting prices.

In the first week or two of December production of pig iron was at the rate of about 22,500,000 tons annually, contrasting with a maximum rate of 31,600,000 tons, reached in February last. Considering, however, that the merchant furnaces curtailed their output much less than the steel interests, it may be estimated that the steel industry in the forepart of December was running at only two-thirds the February gait. Toward the close of December the reduction was so sharp that no precise estimate can be made. The prospects of resumption are uncertain. Some plants are definitely scheduled to resume operations the first week in January, but in other cases there will probably be a wait for some indications of the character of business in the new year.

Among buyers the impression is widespread that finished steel prices will be lower within a few weeks, either through an orderly reduction or an open break. It has been generally reported that the chief desire of the steel interests was to hold prices until after the turn of the year, so that if lower prices were to be sanctioned the point could be reached by an impressive and formal reduction.

Pig Iron.

The market has continued quiet, without any important changes in prices. Demand has been light and it is evident that melters aim to have their obligations at a minimum. Several meetings of blast furnace interests have been held, chiefly at Philadelphia and Cleveland, looking to the exerting of influences for a better market, but no definite conclusions have been reached. There was a particular desire to bring about better conditions in the basic pig iron market in the Central West, but the work so far seems to have been fruitless. Basic iron had, however, firmed up slightly before the movement was definitely proposed, and is quotable at $13.50, valley furnaces, while as low as $13 was done in November. A sale of about 2000 tons of Bessemer was made for December delivery at $15, valley, the regular market since late in August Foundry iron has gone at $13.75 to $14, valley, and one interest has been ready to do $13.50 on particularly attractive business

Steel.

The movement for regular prices on billets and sheet bars was in the first flush at the time last report was written, and since then the understanding has had to yield a trifle at two points. At the time of last report Bessemer billets were quoted at $23 and sheet bars at $24.50, both f. o. b. Pittsburg, plus freight from Pittsburg to destination. The idea now is $23 for billets and $24 for sheet bars, at Pittsburg or Youngstown, with freight to destination from the nearer point. A concession of 50 cents in the spread between billets and sheet bars was made and the separate basing point at Youngstown was re-established. However, the open-hearth steel market seems to have firmed up to the Bessemer level, whereas in November some sales were made at less than the going price for Bessemer. Rods are slightly lower, at $27.50, Pittsburg.

Finished Steel.

The following prices, f. o. b. Pittsburg, except where otherwise stated, are being quite generally observed:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, 1.40 cents for tank quality.

Shapes, 1.40 cents for beams and channels, 3-in. to 15-in., zees, and angles 2 x 3 and larger.

Steel bars, 1.40 cents, base; iron bars, 1.35 to 1.40 cents, Pittsburg; 1.30 cents, Cleveland; 1.30 to 1.35 cents, Chicago.

Wire nails, $1.70, base, per keg; plain wire, 1.50 cents; painted barb wire, 1.70 cents; galvanized barb wire, 2 cents.

Black sheets, 28-gage, 2.20 cents; galvanized, 3.20 cents; painted corrugated roofing, $1.55 per square; galvanized, $2.75.

Tin plates, $3.60 for 100-lb. cokes.

CORRESPONDENCE

Presidency of American Electrochemical Society.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In view of the nomination of officers of the American Electrochemical Society for the year 1911, we, the undersigned, suggest for the office of the president Dr. William R. Whitney.

The abilities of Dr. Whitney as an electrochemist are too well known to need to be stated here. His recognition as a chemist is best shown by the fact that he has been elected to the presidency of the American Chemical Society. His able services as a president of a national society have been shown by his conscientious work as president of the American Chemical Society.

He was one of the two prominent candidates for president at the election of the American Electrochemical Society last year, but declined on the ground that he was then president of the Chemical Society; the reason for his declination last year, therefore, now no longer exists.

We feel that with Dr. Whitney as president of the American Electrochemical Society the interests of that society will be in very able and conscientious hands, and that the duties of that office will be well taken care of.

F. G. Acheson, L. H. Baekeland, H. R. Carveth, Francis A. J. FitzGerald, Carl Hering, F. A. Lidbury, F. R. Taylor.

Heat Loss Through Furnace Walls.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—My attention has been called, by Mr. F. T. Snyder, to a typographical error in formula (4), page 218, Vol. XIV of the *Trans.* Amer. Electrochem. So. in my paper on "Heat Conductances Through Walls of Furnaces," and copied with the same error in the advanced copies of my paper on "Method for Determining Thermal Conductivities" read at the recent Chicago meeting, where it is (6) on page 9. The letter "l" occurring twice in that formula should be the numeral "1."

I take this opportunity to also call attention to the fact that the simpler formula (4) in the latter paper given for a sphere, and (2) in the earlier one, is also rigidly correct for any rectangular furnace and not merely for a cubical one.

Philadelphia, Pa. Carl Hering.

Heat Resistance Units.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In your issue for December appears an article by Mr. Carl Hering on "temperature drop a true measure of thermal resistance," which to my mind is much to the point. Not only are Mr. Hering's proposals logical from a scientific standpoint, but they are directly applicable to everyday practice.

I would propose that instead of using the English inch as the unit cube for thermal resistivity and conductivity the centimeter cube be used. This would give to these specific properties of materials a multiple relation to the corresponding C. G. S. figures. I would further propose that the thermal unit for resistance and conductance be named not thermal ohm and thermal mho, but that as abbreviation of these "thohm" and "mhoth" or "themho" be used instead.

Is it not eminently proper for the American Electrochemical Society to study now the question of nomenclature, as the above, and ratings, etc., and attempt to standardize terms that would be accepted by the profession?

Hartford, Conn. Woolsey McA. Johnson.

Metallurgy of Zinc.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I have read with interest the editorial in the December number, entitled "Condensation of Zinc Vapor," in which the work of Mr. Hixon, Mr. Johnson and others is spoken of. The general trend of the editorial seems to be an encouragement of improving the metallurgy of zinc, the "unusual" metal. It also infers that the present metallurgy of zinc is primitive and not in keeping with twentieth century methods. This attitude is certainly correct.

The serious error in the editorial, however, is the failure to recognize the advance of the dry-chloridization of complex zinc ores, originally invented in this country by Messrs. Chas. E. Baker and Arthur W. Burwell, prefaced in Norway by Alf-Sindig Larsson, and in England by Swinburne and Ashcroft. The process has been further improved in this country by Mr. Chas. E. Baker and others at various times connected with him, such as Mr. William Koehler, once associated with Dr. Hoepfner, Chas. A. Diehl and J. L. Malm. Mr. Malm is at present manager of a works in Georgetown, Col., known as "The Western Metals Co.," licensed under the Baker-Burwell patents by Mr. Baker, owner of the patent rights for Colorado.

It is not my purpose in this letter to describe the process, as such has already been done, both in your journal and in a paper by Mr. Baker before the American Electrochemical Society. It is my purpose to call your attention and that of your readers to the error in your editorial, that while you congratulate Mr. Hixon and Mr. Johnson you omit the Baker-Burwell process, which, I believe, is much nearer commercial fulfillment than any.

The process is particularly adapted to ores carrying zinc-lead-iron sulphides with small quantities of copper, silver and gold, and recovers all the values. As such ores lie on dumps in the West in unlimited quantities, the value of the process as a factor in the "conservation of our natural resources" is of great magnitude. Either spelter or zinc and zinc-lead pigments may be obtained, as desired.

Chicago, Ill. Howard Baker.

[As the editorial in question was entitled "The Condensation of Zinc Vapor," its scope was clearly restricted to smelting processes. That, even with greatly improved smelting processes, there would remain a distinct profitable field for a chlorination process, when properly reduced to practice, there can be no doubt.—Editor.]

The Training of Chemical Engineers.*

BY M. C. WHITAKER.

Much attention is properly being centered upon the education of men in the scientific development and management of agricultural production, and the Government not only gives direct financial support to a large number of schools for such training, but also maintains a Department of Agriculture, the function of which is largely educational.

The annual production of the chemical industries is almost equal in value to the agricultural production of the country, and it is, therefore, proper to compare the facilities now being provided and the means now being adopted for the education of men to develop and manage the widely diversified units of chemical manufacture with the methods and facilities in other educational fields. Obviously the general educational and technical equipment of men to develop and direct processes or works depending upon the applications of chemistry, and usually involving a knowledge of power and mechanical and electrical machinery, is much greater than the technical equipment required for men in agricultural production. While agricultural education has grown and developed at a rate commensurate with the producing power of that industry, and has been fostered by private, state and federal funds, education in the equally important and essential field of chemical manufacture has been, in some institutions, entirely ignored, in others only indifferently provided, and in no single case supported and equipped on a basis comparable with the wealth-producing power of the industry.

Efficient production and the economic management of our manufacturing plants are essential features to our commercial development, and it is in this field that the greatest results are to be attained in the conservation of our natural resources. The accomplishment of these results obviously depends upon the application of scientific knowledge to the solution of all problems, both great and small, in the development, the direction and the management of our factories.

The chemical industries very properly look to the schools for men qualified to produce these results, to improve their production and manage their works. The best evidence that more and better trained men are needed in the chemical industries is the fact that this Institute of Chemical Engineers, composed of men of experience and men now engaged in the direction of great industries, meets twice a year and devotes a large portion of its time to the study of the problem of how to obtain trained men to assist them in the development and administration of their work.

Every employer of chemical talent knows that at best the young graduate is only a vague "prospect" and that much has been left undone in his training.

The problem of proper training and correct methods of teaching chemical engineering is one which must be carefully analyzed and studied from its very foundation and is not one to be remedied by a few trivial changes in existing curricula—by dropping this and substituting that. The subject must be opened up and examined to its foundation, and if it is found that the present structure is built on sand we should put some "concrete" under it.

Necessarily the problem must be solved by the co-operation of the teachers with the employer of chemically trained men, and the writer, having served a term of practically 10 years in each of the above fields, begs to submit a few observations and conclusions for the consideration of the institute committee.

The chemical industries require for their development and management two classes of men of somewhat different training, natural qualifications and range of service.

First.—Research chemists who are qualified naturally and by training to originate and to develop in new fields. The training of the research man is more advanced, or supplements that of the chemical engineer, and the research results furnish the foundations for the industries which the chemical engineer organizes and administers. In other words, the research chemist works in the new and undeveloped fields of chemical knowledge and produces results calculated to contribute new knowledge and new arts.

Second.—The *chemical engineer* works in the organization, operation and management of existing or proposed processes with a view to building up a successful manufacturing industry. He uses his classified knowledge of chemistry and the allied engineering branches in developing, perfecting, organizing and administering a plant or a process for the production of a marketable and useful product at a profit to the investor.

Such a field as this requires a man of knowledge, originality and resourcefulness. His fundamental training in chemistry, physics, mathematics, etc., must be thorough and must be combined with a natural engineering inclination and an acquired knowledge of engineering methods and appliances. His originality and imaginative capacity seem to me to be essential and a combination result of natural qualifications and training. Resourcefulness, however, comes as a result of experience in application and the ability to adapt a wide range of methods and practices to new conditions. A man with the natural qualifications, supplemented by the proper training, may become a successful chemical engineer.

The success of the research chemist is measured by his scientific achievements, whereas the success of the chemical engineer is measured by his commercial results. While their work bears a certain mutual and cyclic relation it must be apparent that their natural and educational equipment may be entirely different.

The development of specialized training in certain selected lines of manufacture is not a proper function for an engineering school, but should be left to the trade schools or to the industries themselves. Specialized research, on the other hand, should be carefully eliminated from the regular engineering training and provided for in graduate courses.

For convenience in discussion I have divided training subjects for the chemical engineer into three general classes: fundamental, associated and supplementary. No attempt is made to discuss the details of the curriculum, the general purpose being to get broad subdivisions as a starting point. The question of arrangement of subjects into a curriculum and the proper allotment of time for the course depends upon what is finally determined as proper training for the men under discussion:

Chemistry Physics Mathematics Allied subjects	Fundamental training.
Electrical engineering Mechanical engineering Civil engineering General engineering Business economics	Associated training.
Study of the *applications* of the fundamental and associated training in laboratories equipped with the "tools of the trade" and with working plants. Training by "contact" and by "example" in a laboratory managed as an approved business, in the principles and practices of efficient organization and administration.	Supplementary training.

Fundamental Training.

The training in the fundamental subjects need not be materially changed except perhaps more attention should be given

*A paper read before the American Institute of Chemical Engineers at the meeting in New York City on December 7.

to laboratory facilities and to the selection of instructors for the fundamental work. Profound scholarship and a record for original research work are too often made the sole determining factor in the selection of teachers for these subjects.

Research qualifications are of secondary importance in the selection of men to give the fundamental training to our chemical engineers. Such teachers might better be chosen from men physically, temperamentally and educationally qualified to present their subjects clearly, logically and enthusiastically to the student, and to present them in such a way as to quicken and hold his interest.

Too often our undergraduates become muddled, discouraged and even give up a subject because of its dry, disconnected presentation or because the instructor "talks over their heads" or lacks the personality and the power to interest them. Research instructors are often permitted to emphasize their "hobbies" or teach their special experiences without regard to the purpose of the course and its relation to the fundamental training. Our instructors should always be chosen to fit the course requirements and should not be permitted to divert the work into special fields not contemplated in the basic formulation.

The training in the fundamental branches should be more thorough and carefully proportioned than at present, keeping in mind that the chemical engineer's knowledge must be classified, complete and accurate in the broad principles and not statistical, encyclopediac or of the class of deep profundity required for research in new and original fields. The chemical engineer's knowledge is to be used as a basic "tool" of his trade and may be given as such without detracting one iota from its value as a mental training.

Associated Training.

Associated training is for the purpose of placing in the hands of the chemical engineer a working knowledge of the other engineering branches so that he may utilize them in the development and management of his particular problem. Courses designed primarily as foundational for future advanced study in the same field are not likely to be proper courses for this associated training. Our associated courses should be broad and general, and need not carry the student beyond the foundational principles of the subjects with a working knowledge of the existing design, construction, materials, operation and use of engineering appliances.

The existing methods of teaching by lectures, demonstrations and laboratory work, combined with a liberal use of text and reference books is probably the most effective way of reaching the fundamental and the associated subjects.

Assuming that the student now has a thorough fundamental foundation in the basic principles of his profession and a working knowledge of the associated engineering branches schools should be equipped for *directed* study of their *applications* to the problems of manufacture and production. This applied study is classed as "supplementary training."

In the education of teachers, in the education of doctors, in the study of agriculture, and in the education of all other engineers except chemical engineers, training in the *application* of the respective fundamentals, under the direction and with the assistance of experienced teachers, is considered essential. Medical schools without hospitals, teachers' colleges without practice schools, schools of agriculture without experimental farms, or engineering schools without laboratories and shops would hardly be dignified by classification as schools. Such institutions invariably invest large proportions of their resources in facilities for demonstrating the proper practical applications of the fundamental theories.

Is there any reason why chemical engineering should not and could not be taught by the tried methods of the normal schools, the medical schools, the agricultural schools and other engineering schools? Only with proper chemical engineering laboratories, equipped with real working models of standard appliances to illustrate the basic applications of the industries and a proper curriculum arrangement to permit the student to study and use these appliances and the principles involved in their application will we be on a basis comparable with the methods and the facilities now existing in other educational fields.

But we can accomplish still more with proper laboratory facilities. We can so construct and administer these laboratories that the student will be surrounded by an "atmosphere" of manufacturing and business efficiency, where he will learn by example, by daily contact, by "attrition," the modern methods and practices of office and works management. Chemical engineers should have this knowledge. It is fundamental to the proper fulfilment of their job. Instances where failure has been converted into success and industries saved by a knowlege of proper administrative practices, and the application of business and works efficiency methods, are too numerous to mention. Refinements in chemical processes and ingenious mechanical devices are all ineffective and often useless if inefficient organization and management are permitted to absorb the earnings. Successful chemical manufacturing is based upon three general principles: First, chemical and physical facts; second, mechanical applications; third, organization and management.

The first principle is definite and basic, and is, therefore, not capable of variation, but the second and third are variable and may be far from perfection. The greatest opportunity for increased profit therefore lies in the possibility of mechanical improvements and improvements in the efficiency of the organization. Instruction is provided in a greater or less degree in existing schools in the two first principles mentioned, but the third equally important and fundamental principle is not even undertaken.

The "contact" system which I am urging for adoption as a method for teaching the principles and the applications of chemistry to manufacture, and for imparting a knowledge of the principles and practices of efficiency in organization, management and administration, are the same as the methods which have always obtained, by force of circumstances, in country schools, where the small children in the A, B, C classes unconsciously absorb geography, history, arithmetic, etc., by hearing, seeing and being in the "atmosphere" of the more advanced work. This method can be adopted in the training of chemical engineers and can be made infinitely more effective than in the country school.

The "contact" or "frictional" method would require a laboratory plant larger and more comprehensive than anything yet established, and would have to be managed on somewhat different lines than those now obtaining in engineering schools.

If it is proposed to direct the student in the study of the applications of fundamentals of factories, factory appliances, factory processes and manufacturing business by the "frictional" method, the laboratory should be equipped, organized and administered as a live manufacturing proposition. There should be ground space enough to permit of the erection of one or more complete operating plants in addition to the general laboratories for the study of great applications, such as distillation, evaporation, filtration, wet reactions, high temperature oxidation, electrochemistry, etc.

The complete plants should be chosen from some of the important chemical processes of great common interest, which at the same time illustrate a wide diversity of chemical principles, appliances and products—for example, the manufacture of gas.

These plants should be designed and built from the foundation to the roof so that the structure itself, materials used, equipment and arrangement would illustrate the best known practice and permit of the most economical management and operation. Every structural detail should be provided with a view to educating by example. Office appliances, office sys-

tems and facilities should be provided, and the equipment include books, trade journals, patent literature, samples, advertising matter, house organs, etc., of the business. Conference facilities should be provided in each laboratory for lectures, discussions, demonstrations of the chemical, mechanical and business features of the process. All such work should be conducted in the special laboratories, and the student from the time he enters until he leaves should be made to "stumble over" the tools of his art and become "saturated" with the "atmosphere" of the business from the raw material to the market.

The classes should "go the rounds" of the laboratories in convenient sized sections for conferences and for "manning" the work.

In connection with the chemical engineering laboratory there should be a "shop organization" consisting of competent mechanics, helpers and laborers necessary for the upkeep of the plant, and this organization should be so administered that our students would gain actual experience in dealing with workmen. Office experience, correspondence, dictation, filing and recording, fundamental costing, etc., may all become familiar knowledge to the student by having these facilities arranged for his use and by incorporating them in his daily "business."

Technical Advisers.

These laboratories of engineering chemistry should be organized with a system of technical advisers to be selected from representative experts in each typical field of industrial chemistry. These advisers should be specially qualified experts or active works' managers of live concerns. Their connection with the laboratory should not be merely nominal, but should carry with it a responsibility for the proper equipment of the special laboratory of the industry which they represent. They should also give some lectures upon their specialty, not altogether from the chemical standpoint, which presumably can be covered by the regular instructors, but from the business, organization, and relative industrial standpoint.

The personal contact and acquaintance between adviser and student is an obvious mutual benefit. The attitude of the leading industries toward such a chemical engineering school would become one of personal interest instead of one of criticism.

The technical advisory system, if properly initiated and administered, will ensure modern equipment, methods and instruction in chemical engineering, and will give, through the lectures, first hand and accurate general information on the scope and magnitude of the typical industries. Furthermore, it will definitely dispose of the frequent reference to obsolete and antiquated methods and equipment. By relying upon the judgment of these experts and managers of live and paying industries we would avoid the equally dangerous extreme of becoming loaded up with impractical, untried appliances and uncommercial processes.

Industrial Research.

The largest industrial corporations, such as the General Electric Company, the United Gas Improvement Company, the National Electric Lamp Association, etc., have established and are maintaining research laboratories. These laboratories are directed in their chemical and physical research by able and high-priced men, and are equipped and maintained at great expense.

Such laboratories are being established because there are no existing equipments, on a suitable scale, for solving the problems necessary for their industrial advancement. The corporations have not undertaken the burden and expense of academic research from choice, but from necessity. Our scientific institutions have utterly failed to provide the facilities for industrial research, and as a consequence are being "elbowed" aside from their natural position of technical and scientific leadership.

Under existing conditions the small manufacturer who cannot afford to equip and maintain a research laboratory has no prospect of solving his industrial problems. Unless the scientific institutions develop modern chemical engineering laboratories, equipped with the tools of the industries, and place their facilities within the range of the small manufacturers, industrial development will be limited to the few concerns whose means will permit the establishment and maintenance of laboratories for private research.

On the other hand, with such laboratories as I have outlined, equipped with every facility for experimentation on a large scale, factory managers, technical laboratories and individuals could be interested in availing themselves of these facilities and in establishing researches for solving industrial problems.

Frequent reference has been made to the cost of such a laboratory of engineering chemistry as has been outlined We are dealing with a great industry and a great problem, and we should therefore exercise our sense of proportion. It is estimated that the minimum net profit of chemical manufactures is $300,000,000 annually. It is also estimated that the combined investment in chemical engineering equipment in all of the educational institutions of the country is not over $30,000, or one hundredth of 1 per cent of the net profit of the industry for one year. A $30,000 investment, or even one hundred times that, is an absurdly small equipment to be devoted exclusively to instruction in the application of chemistry for such an enormous and profitable industry, not to mention the facilities for research development. If the plan outlined will produce men better qualified to enter this field of industry, and men who can "deliver the goods," the question of cost will never prove an obstacle to the development of such laboratories of chemical engineering.*

Columbia University.

North Dakota Lignite has been tested as a fuel for power purposes at the plant of the Wiliston irrigation project of the United States Reclamation Service. The boiler used was of the standard Stirling water-tube type, consisting of three steam drums, one mud drum and three nests of tubes. The conclustions drawn from the test are that steam can be made with a fuel efficiency of 55 per cent to 58 per cent of the heat in the coal, and no difficulty is experienced in getting the full capacity of the boiler. The results compare favorably with those obtained in the average plant using a good grade of bituminous coal, when the heat available to the boiler is considered. Reduction of the moisture in the coal seems to improve economy, but the tests were not sufficient in number to determine definitely the condition of the fuel and time required for weathering to secure the best results. The steam blower for the ashpit is inefficient and there is no gain in supplying superheated steam to it. A saving in steam with equally good results could probably be obtained by substituting a fan. A complete statement of the test is contained in *Bulletin No. 2* of the Bureau of Mines, Washington, D. C.

---

*At the close of this lecture Prof. Whitaker presented a series of concrete questions which will be submitted to all members of the American Institute of Chemical Engineers for a mail vote. These questions are as follows:

(1.) Is the definition of a chemical engineer and the outline of his requirements substantially correct? (2.) Is the prevailing system of education adequate to produce the chemical and engineering talent needed in the industry? (3.) Does the present method of training chemical engineers produce men comparable in their respective qualifications with civil, mining and mechanical engineers? (4) Do factory managers find our graduates qualified to assist in building up and developing the business or are they simply "prospects" who must be "educated" at the expense, in time and money, of the industry employing them? (5.) Are men who receive their experience in the application of the fundamentals in the works where they are employed narrow in their perspective and limited in resourcefulness? (6.) Is there any reason why chemical engineering should not be taught by instruction in the applications of the fundamentals, in a similar manner to other educational systems? (7.) Are the subjects included under "supplementary training" desirable or essential, and is the "frictional" method suggested a proper way to present them? (8.) Would a laboratory of engineering chemistry, equipped and managed as outlined, maintaining a rigid standard for entrance and for graduation, come nearer fulfilling the needs of men in the chemical industries? (9.) Would manufacturers avail themselves of the facilities of such a laboratory for industrial research? (10.) Should such a laboratory be organized and administered, both in its relation to the students and to its work, as a live, up-to-date business?

What Is "Cyanamid"?

By John Woods Beckman.

At the present time there are three different substances that go under the name of "cyanamid." But only one of these has a legitimate right to the name, the two others are illegitimate sisters to this one

The substance with the right to the name is one whose chemical formula is $H_2N{-}CN$, and the name of cyanamid indicates to the chemist that an amid (NH_2) group is combined with a cyanogen (CN) group forming cyan-amid.

Cyanamid is produced in the following manners

Cyanogen chloride is introduced into a solution of ammonia in ether, and cyanamid is formed according to the following formula.

$$CNCl + 2\,H_3N = CN.NH_2 + NH_4Cl.$$

If tio-urea is treated with the oxides of lead or mercury in an aqueous solution, cyanamid is formed, and the reaction can be written in following manner:

$$NH_2CS.NH_2 = CN.NH_2 + H_2S.$$

Also if a cyanamid salt be treated with an acid under special conditions cyanamid will be produced.

Pure cyanamid is a white, crystalline, delinquescent mass, soluble in water, alcohol and ether. It melts at 40° C. One characteristic feature of cyanamid is its tendency to polymerize, forming di-cyandiamid, and even higher products of polymerization, such as melam. The polymerization of cyanamid takes place when a solution of cyanamid is being concentrated or being kept for any length of time. If cyanamid be heated to 150 C. it polymerizes with great violence.

Chemically cyanamid can be either classed as weak acid or as a weak base. As an acid it will form salts with metals, such as silver, calcium and others. Of these salts the calcium salt is the most important. As a base, cyanamid will form a number of salts; with acids these salts as well as most of the metal salts are very unstable.

Cyanamid, as well as a number of its salts, is an unstable chemical complex that very readily transforms if conditions are right in two different directions, polymerizing forming dicyandiamid, or hydrolizing forming urea.

The substance that is most generally known by the name of "cyanamid" is the product obtained in the process of fixing atmospheric nitrogen with calcium carbide. "Cyanamid" is the name most generally used for this compound, but a trade name of "lime-nitrogen" for this product is being used. The only right "lime-nitrogen" has to the name of "cyanamid" is that one of the components of the product is a calcium salt of cyanamid.

The chemical formula for "lime-nitrogen cyanamid" can only be expressed in the following manner.

$$xCaCN_2 + yCaO + zC + uCaC_2.$$

From this formula it will be readily seen that this compound is a heterogeneous substance and of no definite chemical composition, nor do its components appear in the same ratio all the time.

To explain the composition it is necessary to give, in brief, the chemistry of the formation. If calcium carbide is heated in an atmosphere of nitrogen, the carbide combines with the nitrogen with great avidity, according to the following formula:

$$CaC_2 + 2\,N = CaCN_2 + C.$$

This reaction explains the existence of free carbon in the graphitic modification in the "cyanamid," while the free CaO is an unavoidable admixture The carbide used for the fixation of the nitrogen contains a considerable amount of free CaO as diluent, and this naturally will appear in the finished "cyanamid." A small amount of carbide is unavoidable, as it is impossible with the present state of the art to totally bind all the carbide within reasonable time

The chemical nature of "cyanamid" or lime-nitrogen" is a very complex question, and even more so than for the pure cyanamid NH_2CN, on account of the unavoidable CaO. An Italian agricultural chemist by the name of Ulpiani has made some very extensive researches on "lime-nitrogen," and has found that "lime-nitrogen" is permanently changing it chemical structure, even only by storing same and under the influence of ordinary atmospheric conditions. What part the air-slacking of the lime may play in this chemical rearrangement of the chemical structure of "lime-nitrogen," or, more correctly, the calcium salt of cyanamid, is very hard to determine. The calcium cyanamid is of an unstable structure and forms with great ease polymerized as well as hydrolyzed compounds

In treating the "lime-nitrogen" with water, even with small amounts, still more complex phenomena take place, basic as well as acid calcium cyanamid salts are formed, with the free lime present; urea is formed; calcium cyanamid carbonate may be formed, and a quantity of others, including dicyandiamid and free ammonia.

Ulpiani has made very extensive researches regarding the action of "lime-nitrogen" with various different acids and in various solutions, and these are able to spread a good deal of light over an exceedingly complex chemical problem, which is growing more and more important as new uses for "cyanamid" are developed.

These researches of Ulpiani have shed some light on the fertilizing value of "cyanamid," and he proves quite conclusively that it is not cyanamid or dicyandiamid that is the direct fertilizing ingredient in "lime-nitrogen," but it is the result of hydrolization, the urea, which is acted upon by the bacteria, and ultimately transformed into a nitrogen compound that can be absorbed by the plant.

The third product that claims the name of "cyanamid" bears it only as a trade name. "Lime-nitrogen" is mixed with a certain per cent of sodium nitrate and with a low-grade nitrogeneous material as a diluent to regulate the nitrogen contents of the finished product, and is then called "cyanamid." This material is compounded exclusively for the fertilizer trade and is of no chemical importance.

It is apparent from the above that the name of "cyanamid" is one that has lost its original meaning and has come to indicate altogether different substances to different groups of people.

The name "cyanamid" should stand for the chemical compound known by the following formula, H_2CN_2.

"Lime-nitrogen," although a meaningless name, as meaningless as if gypsum were called "lime-sulphur," may remain the name for the product now generally known as "cyanamid," while for the third product a name like "cyanamid compound" or "lime-nitrogen compound" would probably answer, thus clearing up a question of names that is becoming more and more complex the wider the field stretches in which "lime-nitrogen" can be used.

Niagara Falls, Canada.

Copper-Aluminium Alloy.—A new alloy, believed to consist essentially of copper and aluminium, is being placed on the market under the trade name of cupsor by the Cupsor Company, of 50 Church Street, New York City. It has a color like gold, polishes readily and acquires a brilliant luster and is, therefore, especially adapted for jewelry (watch cases, etc.), and all ornamental purposes. It is further claimed to be highly resistive to chemical influence. Not only is it said to be immune from the attack of the ordinary atmosphere, from salt water and salt air, but it is claimed that sulphuric acid, hydrochloric acid, lemon juice, tomato juice, vinegar, etc., have no effect on cupsor. Cupsor can be readily machined and is easily rolled and drawn into wire. "The tensile strength of cupsor in the casting is estimated to be at least 80,000 lb. to the square inch. The No. 20 gage hard-drawn wire broke in a recent test at 138,550 lb. to the square inch." The specific gravity is 8.11.

Thermal Resistance and Conductance; the Thermal Ohm and Thermal Mho.

By CARL HERING.

In the preceding issue of this journal (page 676) the writer showed that the degree of temperature and the watt may be conveniently and correctly used to express and measure thermal resistances and conductances, respectively; also thermal resistivities and conductivities. Moreover, they are true mates, as they are numerically the true reciprocals of each other. Hence we have at our disposal two simple, well-known and named units which can be used in such thermal calculations.

The only objection to them is perhaps best shown by the better known electrical analogy. Suppose the ohm had not been named as a separate and independent unit of electrical resistance, and that we therefore were compelled to express and measure resistances in our calculations, in volts, that is, in terms of the number of volts which would be required to cause 1 amp to flow through that resistance. The unit of resistance (equal to the one now called the ohm) would then naturally be 1 volt, hence numerically equal to the unit of e.m.f. This would, of course, be quite correct, and calculations would give the same results as they do now with the ohm, but it would be confusing and more cumbersome; it is mentally disturbing to measure a resistance in terms of volts, because we know that volts represent a different physical quantity than resistances. It unquestionably gives us a greater mental comfort to give this same unit of resistance a name of its own, and one which is different from the unit of voltage, because it is a different physical quantity.

Ohms are equal to the ratio of the volts to the amperes; to measure a resistance in volts is, therefore, making the denominator of this ratio unity so that the numerical value of this ratio is then equal (numerically, but not physically) to the numerator. It is, therefore, a correct expedient to use when we have nothing better. But in electrical calculations it has been found very convenient to create something better, namely, the ohm; it changes nothing, as the unnamed unit is equal to the ohm; it is, therefore, merely adopting a name.

The above analogy applies very perfectly to thermal resistances. It was shown in the article referred to that thermal resistances can be correctly expressed and measured by the drop of temperature for a unit flow of heat (1 watt) just as electrical resistances could be measured by the drop in volts for a unit flow of current (1 amp). But why should we involve in thermal calculations the mentally disturbing features of measuring a thermal resistance in degrees of temperature when we know that physically they are two different quantities? The same is true of watts and conductances. Why not do as was done in electrical mensuration, give these same units names; it will not change anything else; quantitatively they will remain the same.

The purpose of this article is to urge that this be done, namely, that a name be given to the unit of thermal resistance which was shown in the previous article to be the most rational unit, and one which gives the simplest possible relations, namely, unit relations, just as in electrical calculations. Calculations of thermal flows would then be precisely as simple as the electrical ones made with Ohm's law; there would be no reduction coefficient to remember or to use, as it would be unity, like in Ohm's law. It would simplify the conception of a unit of thermal resistance.

To select a new name, like that of Peclet, so as to honor those who taught us the fundamental principles of this branch of science, would be following a very good custom. But the number of such new names is becoming great and requires them to be defined. It, therefore, seems a better expedient to adopt a half-way measure, and name this unit the "thermal ohm." This term was originally sugggested by Dr. A. E. Kennelly.

The thermal ohm, as applied to the quantity above mentioned, is then that thermal resistance which will require a drop of temperature of 1° C. for 1 watt of heat flow.

Ohm's simple law then applies numerically to calculations of thermal flows. If R is the thermal resistance in thermal ohms, W is the heat flow in watts and T the drop in temperature in centigrade degrees, then the thermal Ohm's law is

$$W = \frac{T}{R}$$

which may then be unhesitatingly used in calculations, as the units are then such as will avoid all coefficients and reduction factors.

Specific thermal resistances (that is, resistivities) are then expressed in terms of thermal ohms for 1 in. (or centimeter) cube.

The numbers expressing such resistances in thermal ohms will be the same as the numbers expressing the drop in temperature for a unit of heat current, as explained in the previous article; the only change is in the name; instead of saying that the resistance is so-and-so many degrees, it would be said to be the same number of "thermal ohms."

The specific resistance of copper is about 0.1 thermal ohm for an inch cube; that of graphite about 0.3; carbon about 1.0; iron about 0.5; hot firebrick about 44. The total thermal resistance of the walls of a well constructed furnace of about 100 kw might be of the order of about 0.15 thermal ohm, hence according to the thermal Ohm's law the loss through the walls for a temperature of about 1500° C. would be $W = 1500 \div 0.15 = 10{,}000$ watts. Or conversely, if a 10 per cent loss (= 10,000 watts) is to be allowed for such a furnace, then as $R = T/W$, the thermal resistance of the walls must be designed to be equal to $1500 \div 10{,}000 = 0.15$ thermal ohm.

According to this same system thermal conductances should be expressed in "thermal mhos" instead of in watts; they will again be numerically the same as the number of watts. Moreover a thermal conductance expressed in thermal mhos would be equal to the reciprocal of the thermal resistance in thermal ohms, just as the electrical mho is the reciprocal of the electrical ohm.

The definition of a thermal mho then is that conductance which will allow 1 watt of heat flow to pass when the difference of temperature is 1° C.

Conductivities will then be expressed in terms of thermal mhos for 1 in. (or centimeter) cube. They will be numerically equal to those heretofore expressed in watts, and are about as follows for a 1-in. cube: Copper, 10 thermal mhos; graphite, 3.3; carbon, 1; iron, 2; hot firebrick, 0.023. The conductance of the above-mentioned furnace will be about 7 thermal mhos.

These units are, therefore, of a very convenient size to use in calculations. The thermal ohm and mho are, of course, independent of whether inches or centimeters are used, just as with the electrical ohm and mho. In stating resistivities and conductivities, however, it is necessary to state whether the numbers of ohms or mhos refer to an inch cube or to a centimeter cube.

Thermal conductivities and conductances are often stated in books and tables in terms of a unit based on the gram calorie per second, the cubic centimeter, and the centigrade degree; this unit is generally called the c.g.s. unit, and is generally the one understood to be used by physicists when they fail to state which one they are referring to. The reciprocal of this is then necessarily the c.g.s. unit of thermal resistances.

To call these the c.g.s. units is, however, an error; they are not really the true and correct c.g.s. units, or absolute units, notwithstanding their common usage as such by physicists. A transmission or flow of heat, whether by conduction, radiation or convection, is energy (work or heat) per second and is, therefore, a physical quantity of exactly the same nature as power, like watts, horse-power, etc., just as the foot and the meter are both measures of the same physical quantity, namely,

a length But the absolute or c.g.s. unit of power is the erg per second, that is, the dyne-centimeter per second, and not the calorie per second, as assumed by physicists who use the term as above described. This unfortunate error, which is so commonly committed, may, therefore, cause confusion unless an author describes specifically what he means. This confusion is another good reason for abandoning both of them in practical work and using the practical units recommended in this article.

These true c.g.s. or absolute units are, moreover, a very inconvenient size to use in practice The practical units here suggested are the most convenient to use in all calculations involving electrically produced heat, as in electrical furnaces. The common though incorrect c.g.s. unit—that is, the gram calorie unit—is the most convenient to use in practice when the heat is expressed in calories; it is also the most convenient one for the mathematical physicist under the same circumstances. When, however, the physicist's problem involves electric heat, or, more broadly, a flow, radiation or other transmission of energy of any kind, then the most convenient unit for the mathematical physicist is the true and correct c.g.s. unit described above and based on the erg.

The following tables are a complete set of all the conversion factors and relations between these several units, that is, the new units, the gram calorie units and the true c.g.s. units; the reciprocal values of all these factors are given, so as to avoid all divisions by them; the approximate values are within 2 per cent. They have been carefully checked and cross checked. The unit of thermal conductance referred to in the writer's former papers as "watts" is identical with the one herein called the "thermal mho." And the resistance unit referred to in a previous paper as the "degree" is herein called the "thermal ohm."

Table of Conversion Factors.

(Note.—A flow or radiation of heat may be measured in watts, in gram calories per second, or in ergs per second. In this table the term "c.g.s. unit," that is, the absolute unit, refers to the true ones based on the erg per second; those often called "c.g.s. units" and based on the gram calorie are here given under the latter term. The centigrade degree is understood to be meant in all these units.)

Thermal Resistance.

Thermal ohms
= centigrade degrees ÷ watts = degrees per watt.
= 1 ÷ thermal mhos.

1 thermal ohm:
= a resistance requiring 1° C. per watt of flow.
= 4.18617 gram calorie units; approx. 50/12.
= 0.0000001 c.g.s. unit of thermal resistance

1 gram calorie unit:
= a resistance requiring 1° C. per flow of a gram calorie per second
= 0.238882 thermal ohms: approx 24 100.
= 2.38882×10^{-8} c.g.s. units of thermal resistance.

1 c.g.s. unit of thermal resistance:
= a resistance requiring 1° C. per flow of an erg per second.
= 10,000,000 thermal ohms.
= 41,861,700 gram calorie units

Thermal Conductance

hermal mhos.
= watts ÷ centigrade degrees = watts per degree
= 1 ÷ thermal ohms.

thermal mho
= a conductance permitting a flow of 1 watt per degree
0.238882 gram calorie unit; approx 24/100.
= 10,000,000. c.g.s. units of thermal conductance.

1 gram calorie unit
= a conductance permitting a flow of 1 gram calorie per second per degree.
= 4.18617 thermal mhos; approx. 50/12.
= 41,861,700. c.g.s. units of thermal conductance.

1 c.g.s. unit of thermal conductance
= a conductance permitting a flow of 1 erg per second per degree.
= 0.0000001 thermal mho.
= 2.38882×10^{-8} gram calorie units.

Thermal Resistivities.

Note.—These are all the reciprocals of the corresponding conductivity units.

1 gram calorie, cubic centimeter, unit:
= 0.3937 gram calorie, cubic inch, unit; approx. 4/10.
= 0.238882 thermal ohm, cubic centimeter, unit; approx 24/100.
= 0.0940478 thermal ohm, cubic inch, unit; approx. 2/21
= 2.38882×10^{-8} c.g.s. units of resistivity.

1 gram calorie, cubic inch, unit:
= 2.54001 gram calorie, cubic centimeter, units; approx. 10/4.
= 0.606762 thermal ohm, cubic centimeter, unit; approx. 3/5
= 0.238882 thermal ohm, cubic inch, unit; approx. 24/100.
= 6.06762×10^{-8} c.g.s. units of resistivity.

1 thermal ohm, cubic centimeter, unit:
= 4.18617 gram calorie, cubic centimeter units; approx. 50/12
= 1.64809 gram calorie, cubic inch, units; approx. 5/3.
= 0.393700 thermal ohm, cubic inch, unit; approx. 4/10.
= 10^{-7} c.g.s. unit of resistivity.

1 thermal ohm, cubic inch, unit:
= 10.6329 gram calorie, cubic centimeter, units; approx. 21/2
= 4.18617 gram calorie, cubis inch, units; approx. 50/12.
= 2.54001 thermal ohm, cubic centimeter, units; approx. 10/4
= 2.54001×10^{-7} units of resistivity.

1 c.g.s. unit of resistivity:
= 4.18617×10^{7} gram calorie, cubic centimeter, units
= 1.64809×10^{7} gram calorie, cubic inch, units.
= 10^{7} thermal ohm, cubic centimeter, units.
= 3.93700×10^{6} thermal ohm, cubic inch, units

Thermal Conductivities.

Note.—These are all the reciprocals of the corresponding resistivity units.

1 c.g.s. unit of conductivity:
= 2.54001×10^{-7} thermal mho, cubic inch, unit.
= 10^{-7} thermal mho, cubic centimeter, unit.
= 6.06762×10^{-8} gram calorie, cubic inch, unit.
= 2.38882×10^{-8} gram calorie, cubic centimeter, unit

1 thermal mho, cubic inch, unit:
= 3.93700×10^{6} c.g.s. units of conductivity.
= 0.393700 thermal mho, cubic centimeter, unit; approx. 4/10.
= 0.238882 gram calorie, cubic inch, unit; approx. 24/100.
= 0.0940478 gram calorie, cubic centimeter, unit; approx. 2/21

1 thermal mho, cubic centimeter unit:
= 10^{7} c.g.s. units of conductivity.
= 2.54001 thermal mho, cubic inch, units; approx. 10/4.
= 0.606762 gram calorie, cubic inch, unit; approx. 3/5.
= 0.238882 gram calorie, cubic centimeter, unit; approx 24/100.

1 gram calorie, cubic inch, unit:
= 1.64809×10^{7} c.g.s. units of conductivity.
= 4.18617 thermal mho, cubic inch, units; approx. 50/12.
= 1.64809 thermal mho, cubic centimeter, units; approx. 5/3
= 0.393700 gram calorie, cubic centimeter, unit; approx. 4/10.

1 gram calorie, cubic centimeter, unit:
= 4.18617×10^{7} c.g.s. units of conductivity.
= 10.6329 thermal mho, cubic inch, units; approx. 21/2.
= 4.18617 thermal mho, cubic centimeter, units; approx. 50/12
= 2.54001 gram calories, cubic inch, units; approx. 10/4.

The following table of values will show the convenient size of these two units. It has been calculated from the determinations of S. Wologdine given by A. L. Queneau in this journal, September, 1909, page 383. They are recent determinations of the materials of commerce and do not refer to extra pure or inferior grades. The temperature was about 1000° C. Further details and the method by which they were determined are described in that article. The present writer's opinion is that

some of the heat entering the samples in those tests is likely to have been lost before it was measured. If so, the conductivities given would be too high or the resistivities too low. The figure given above for firebrick was taken from recent careful determinations of Clement and Egy; it gives the conductivity about half as great or the resistivity about twice as great as in the following table; the temperatures were about 400° C. to 800° C. The figures given above for electrode materials were taken from the recent determinations of the writer.

	Resistivities in Thermal Ohms		Conductivities in Thermal Mhos	
	cb. in.	cb. cm.	cb. in.	cb. cm.
Graphite brick	3.76	9.56	0.266	0.105
Carborundum brick	4.06	10.3	0.246	0.097
Magnesia brick	13.2	33.7	0.0755	0.0298
Chromite brick	16.5	42.0	0.0606	0.0239
Firebrick	22.4	56.9	0.0446	0.0176
Checker brick	24.1	61.2	0.0415	0.0163
Gas retort brick	24.7	62.8	0.0404	0.0159
Building brick	26.9	68.2	0.0372	0.0147
Bauxite brick	28.5	72.4	0.0351	0.0138
Glass pot	34.8	88.6	0.0287	0.0113
Terra cotta	40.9	104.0	0.0244	0.0096
Silica brick	46.9	119.5	0.0213	0.0084
Kieselguhr brick	52.3	133.0	0.0191	0.0075

As an illustration of the simplicity of the calculations when these units are used, let the inside of a small furnace be 6 in. cube; let the wall consist of a 4-in. layer of silica brick on the inside and 4 in. of firebrick on the outside. The true average cross-section* of the layer of silica brick perpendicular to the heat flow (namely, the geometric mean, that is, the square root of the product of the extreme sections) for the whole furnace will be 504 sq. in. If its resistivity, from the above table, is 47 thermal ohms, its resistance will be

$$R = \frac{r \times l}{S} = \frac{47 \times 4}{504} = 0.37 \text{ thermal ohm.}$$

A similar calculation for the outside layer of firebrick having a resistivity of 22 thermal ohms gives its resistance as 0.048 thermal ohm. Hence, the total is the sum of these two, which is 0.42 thermal ohm. Incidentally, it shows what a very much smaller insulating effect this much larger outside layer has.

Suppose the drop of temperature through the wall to be 1500° C. Then, according to the thermal Ohm's law, the loss of heat will be

$$W = \frac{T}{R} = \frac{1500}{0.42} = 3580 \text{ watts, or about } 3\tfrac{1}{2} \text{ kw.}$$

This seems high, but the writer fears the resistivities of Wologdine are too low. The heat resistance at the joint, which has not been taken into account, will reduce this loss somewhat. If the arithmetical average cross-section had been used, as is more usual, the calculated loss would have been nearly 50 per cent greater, hence greatly in error.

If it is desired to know the temperature at the joint, then according to Ohm's law the drop of temperature in the inside layer will be

$$T = WR = 3580 \text{ watts} \times 0.37 \text{ thermal ohm} = 1325°.$$

Hence the temperature will be 1325° less than in the inside. As a check the drop in the outside layer will be 3580 watts × 0.048 thermal ohm = 175°, making the total 1325 + 175 = 1500°. This again shows how much smaller the insulating effect of the outside layer is.

To have used conductivities in the above calculations instead of resistivities would have made them quite tedious and much longer.

*"Heat Conductances through Walls of Furnaces." Hering. Trans. Amer. Electrochem. Soc., Vol. 14, 1908, p. 215. This Journal, Vol. VI, p. 495.

The Tooele Smelter.*

BY C. H. REPATH AND A. G. MCGREGOR.

The Tooele smelter is situated about four miles east of Tooele City, Tooele County, Utah, and by rail 41 miles from Salt Lake City. The smelter is connected by its own railroad (the Tooele Valley Railroad) with the San Pedro, Los Angeles & Salt Lake Railroad, the junction being about seven miles from the smelter site. The smelter is located upon a hillside, which makes it possible to a large extent for the level of delivery of the product of one building to be the level of charge floor of the next succeeding one.

The Ores.

The ore treated comes principally from the mines of the Utah Consolidated Mining Company in Bingham Canyon. These mines in Bingham Canyon are connected with the smelter by an aerial tramway, four miles long, having a capacity of 125 tons per hour. Custom ores from other mines are received over the San Pedro Railroad and the Tooele Valley Railroad.

FIG. 1.—TOOELE SMELTER. BLAST-FURNACE BINS AT LEFT, SAMPLING AND CRUSHING PLANT IN CENTER, ROASTED ORE BINS AT RIGHT.

Receiving Bins.

The receiving bins are constructed of steel, and are fireproof throughout. The receiving bins have a capacity of 10,000 tons of ore and coal. The bins are so located and arranged that they may be served either by the 50-ton electric larry cars, which deliver the ore from the tramway terminal, or by standard railroad cars.

Sampling Mill and Crushing Plant.

This building is of steel and concrete throughout. It is 40 ft. x 84 ft. in plan and is five stories high. The mill is composed of two sections and each section has a crushing and sampling department. The ore from the receiving bins is automatically fed upon belt conveyors which convey it to shaking grizzlies that discharge the coarse ore into the crushers. The ore from the crushers is elevated to the top of the building by bucket elevators. In the sampling department the ore is cut four times by Brunton automatic samplers, cutting out one-fifth of the amount each time and discarding four-fifths so that of each ton of ore crushed a sample weighing 3.2 lb is obtained.

The sampling department of each section of the mill contains besides a 12-in. x 24-in. Blake crusher, which is common to the crushing and sampling department:

One O-A sampler.
One 20-in. x 10-in. crusher.
One 1-A sampler.

*A paper read before the Utah Society of Engineers.

One 48-in. x 12-in. rolls
One 2-A sampler
One 26-in. x 15-in. rolls
One 4-A sampler

The discard from the sampling machines drops into screens of the crushing department, from which it is conveyed to the roaster bins. The final sample is quartered by a quartering shovel, the resulting sample is then dried on a steam dryer, ground in an Englehardt sample grinder, and again ground in a Braun pulverizer, so as to pass through a 100-mesh sieve

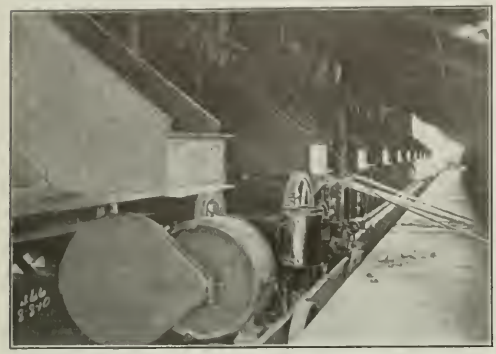

FIG. 2.—CONVEYOR FEEDING MACHINE.

The 100-mesh product is put up in three sample packages, one of which goes to the smelter laboratory for analysis, one to the owner of the ore, and one is filed away for use in case of a dispute.

The crushing department of each section of the mill contains:

One 12-in. x 24-in. Blake crusher.
Two 15-in. x 9-in. crushers
Two 48-in. x 14-ft. screens.
Two 48-in. x 12-in. rolls.

From the crushing plant the crushed and sampled ore is conveyed by belt conveyors to the McDougal roaster steel receiving bins, which have a capacity of 5700 tons. If it is desired the coarse ore after being sampled may be conveyed to the blast furnace steel receiving bins, which have a capacity of 3500 tons.

A blast furnace has not yet been installed, but provision has been made for it.

Roaster Plant.

From the roaster ore bins the ore is automatically fed upon a conveyor system which conveys it up to and discharges it directly into the McDougal furnace charge hoppers. The ore in transit from the bins to the roaster plant passes over a Blake-Denison automatic and continuous weighing and recording machine, which accurately weighs all the ore delivered to the roaster plant.

The roaster plant consists of two buildings, each 64 ft. x 162 ft. Each building contains 16 McDougal calcining furnaces of the Evans-Klepetko type. These furnaces have six hearths 16 ft. in diameter and are 18 ft. high. They have revolving water-cooled shafts and arms, driven by a suitable gearing from the bottom. The rabbles are so set as to move the material from the circumference to the center and vice versa on alternate hearths until it finally drops into the calcine hoppers immediately over the tracks of the electric tramming system for transportation to the charge floor of the reverberatory building. No fuel is used other than the sulphur in the crushed ore, the burning of which furnishes sufficient heat to do the calcining. The gases are taken through flues into the large brick and steel dust chamber, which is 120 ft. x 140 ft. x 40 ft. high. This dust chamber is so arranged that the bottom forms a series of hoppers. The entire contents of the dust chamber can be drawn into flue-dust cars of the electric tramming system and conveyed directly to the reverberatory furnaces for smelting. Each of the 32 McDougal furnaces has an approximate capacity of 45 tons in 24 hours.

Reverberatory Plant.

The reverberatory plant consists of three buildings joined together; the reverberatory charge building, containing the ore and coal hoppers over the furnaces, 66 ft. x 280 ft.; the reverberatory furnace building, covering the larger portion of the furnaces, 82 ft. x 280 ft., and the boiler house, 36 ft. x 326 ft. The latter at the present time contains four 746-hp waste-heat boilers and three 350-hp hand-fired boilers. The boilers are all of the Stirling water-tube type. The reverberatory plant contains five coal-fired reverberatory furnaces, the hearth dimensions of which are 19 ft. in width by 102 ft. in length, with a grate area of 7 ft. x 16 ft. These furnaces have a maximum capacity of 300 tons of calcine in 24 hours on natural draft. The fuel used is Diamondville coal, shipped from the mines in Wyoming owned by the Washoe Copper Company. The coal is dumped from large railway coal cars or from cars of the electric tramming system into hoppers that have five points of discharge, directly over the firebox. The flame after leaving the furnace passes through a 746-hp Stirling boiler, which reduces the temperature of the gases going to the main flue to about 600° Fahr. By this means approximately 600 boiler horse-power are obtained from each furnace from the waste heat. The ashes from the furnace firebox fall into hopper cars of the electric tramming system and are hauled away to the ash dump. The slag is skimmed from the reverberatories twice in eight hours. It is allowed to accumulate until its depth is from 3 in. to 4 in. above the skimming plate in the front of the furnaces, and then skimmed into slag cars having a capacity of 225 cu. ft., which are hauled to the slag dump over the electric tramming system. The matte is tapped from the side of the furnaces through a copper tap-hole plate and run through cast-iron launders directly into the converter building.

One of the waste-heat boilers referred to above has been

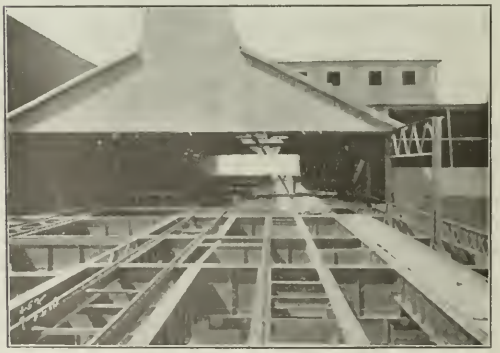

FIG. 3.—REVERBERATORY CHARGE TRACKS.

equipped with a superheater. The superheater is just at the rear of the boiler. In case it proves satisfactory the other waste-heat boilers can each be equipepd with one.

Converter Plant.

The main converter aisle of this plant is 65 ft. x 408 ft., and the casting shed is 52 ft. x 255 ft. The main converter aisle contains five converter stands for 96-in. x 150-in. converters and the converter-lining department. The converters used are of the horizontal barrel type and are 96 in. in diameter by 150 in. in length. The convereters are electrically operated. The main aisle is served by one 60-ton electric traveling crane.

The casting department is served by a 30-ton electric traveling crane. As stated previously, the matte is received in launders directly from the reverberatory furnaces. The end sections of these launders are pivoted so that the matte may be poured

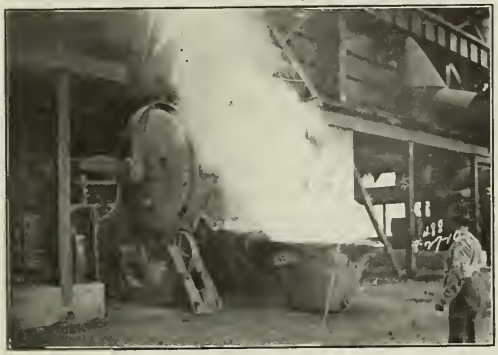

FIG. 4.—SKIMMING FIRST CONVERTER.

directly into the converter opposite a reverberatory furnace, or the launder may be turned so that the matte will fall into a ladle and be transferred to any of the other converters in the building. The slag from the converters is poured into unlined cast-steel ladles and transferred to the reverberatory furnaces by means of overhead cranes. There are two of these cranes, of 12½-ton capacity each. The blister copper is poured into a ladle and transferred by the crane and transfer car to the casting department. In the casting department the ladle is handled by a crane and its contents emptied into anode molds, which completes the operation of producing pig copper. The pig copper contains 99 per cent copper and the gold and silver. It is shipped East, where it is further refined and the gold and silver extracted.

Converter Lining.

The converters are lined in the main converter building, but the lining material is prepared in a building, 24 ft. x 40 ft., adjacent to the ore-crushing plant and receiving bins. The lining material contains a high percentage of silica, having gold and silver values. The material is crushed by the crushers in the crushing plant, and conveyed to a 7-ft. dry pan and pug mill in the clay and silica-mixing and grinding plant. The product of the pug mill drops directly into a bin over the electric tramming system, from which it is transported in cars to the converter-lining plant. The lining plant at the converter contains a 7-ft. grinding and mixing pan. From the grinding pan the material is transferred to the converter, where it is tamped around a cast-iron form by a special Ingersoll-Sergeant tamping machine, 5 in. diameter by 20 in. stroke. The tamping machine is supported by a revolving jib crane, the vertical motion of which is controlled by an electric hoist. After lining the converter is removed to its stand, where it is dried.

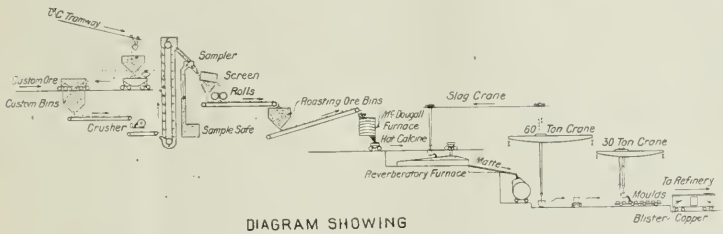

DIAGRAM SHOWING
FLOW OF MATERIAL THROUGH TOOELE PLANT

Smelter Power Plant.

The smelter power-plant building is of brick and steel, the main aisle of which is 52 ft. x 240 ft. It has a lean-to 30 ft. x 90 ft. for the steam auxiliaries, and one on the other side, 30 ft. x 60 ft., for the switchboard and transformer. The building contains the various power engines, blowing engines, compressors and auxiliaries and is equipped with an overhead electric traveling crane.

The building contains:

One 16-in. x 32-in. x 36-in. Corliss engine direct-connected to a 250-kw, 500-volt, direct-current generator.

One 15-in. x 30-in. x 36-in. Corliss engine direct-connected to a 250-kw, 500-volt, direct-current generator.

Two 18-in. x 26-in. x 40-in. x 24-in. vertical, triple-expansion engines, each direct-connected to one 750-kva, 2200-volt generator.

One 15-in. 30-in. x 36-in. x 42-in. blowing engine.

One 26-in. x 52-in. x 52-in. x 48-in. blowing engine.

One 13½-in. x 26-in. x 26-in. x 15-in. x 36-in. steam-driven air compressor.

One 26¼-in. x 15¼-in. x 18-in. motor-driven air compressor.

One 200-kw motor-driven direct-current generator.

One 50-kw motor-driven exciter generator.

One engine-driven 50-kw exciter generator.

Two feed pumps having a total capacity of 678 gal. per minute.

One fire pump of 750 gal. per minute.

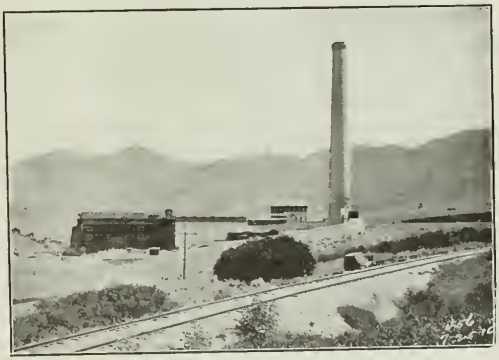

FIG. 5.—FLUES AND STACK.

Besides the above the plant contains the necessary condensers, vacuum pumps, feed-water heaters, traps, etc. The steam for these engines is furnished by the waste-heat boilers and hand-fired boilers adjacent to the reverberatory building.

The engine-driven generators, in addition to furnishing power for the various motors about the plant, will also furnish power for driving air compressors and for hoisting and pumping purposes at the mines of the Utah Consolidated Mining Company.

A cooling tower of the natural-draft type has been constructed for cooling the water from the power-plant condensers and for cooling the water for the McDougal roasting furnaces. The tower is 49 ft. high, and at the base is 20 ft. wide by 140 ft. in length.

Electric Tramming System.

The equipment of the electric tramming system consists of three 7½-ton and two 18-ton locomotives and 50 cars.

Flues and Stack.

The main flue which conveys the gases from the reverberatory furnaces and converters is 20 ft. wide x 18 ft. high x 1360 ft long. One section of the converter flue is 8 ft. wide x 12 ft. deep and 248 ft long; the other section has a cross-sectional area of 132 ft. and is 181 ft. long. Both sections are provided with hopper bottoms and chutes for removing the flue dust. The roasting-plant flue is 16 ft. x 16 ft. and is 255 ft. in length. The main and roasting-plant flues are rectangular in section and of brick and I-beam construction, while the converter flues are constructed entirely of steel.

The stack is 25 ft. inside diameter at the top by 350 ft. in height above the base.

The water for various purposes in the smelting plant is obtained from Pine Canyon. The water is conveyed by gravity from a dam in the canyon through a 12-in. pipe approximately 5000 ft. to a standpipe of 50,000-gal. capacity at the plant. The water is distributed from the standpipe to the various departments.

The Status of Metallurgy in Colorado in 1910.

Editorial Correspondence.

Progress in metallurgy in Colorado during 1910 was not marked by any notable innovations, although it is probably true that foundations were laid on which a prosperous industry can be raised in the next few years. The principal subject attracting attention late in the year was the possibility of reviving the mining industry in the State, from which it may be properly inferred that mining and its allied industry metallurgy have been declining for several years past and reached so low an ebb during 1910 as to attract the serious attention of those most concerned.

The decline and low ebb have been the result of a combination of causes, no one of which can be assigned as the sole cause of the condition. The decrease in quantity and quality of smelting ore, coupled with the failure of mine owners to anticipate this outcome and seek new and cheaper methods of treatment ere it arrived, may be given as the principal causes contributing to the present condition of the industry in Colorado. That there are still great possibilities in mining, however, and that metallurgy will play a large part in the success of the future may be gathered from the following presentation of the situation.

Smelting.

Smelting was the pioneer metallurgical process used in Colorado and constituted a thriving industry until the last decade, during which time it has steadily declined. In 1910 the American Smelting & Refining Company had in operation four Colorado plants: Globe (Denver), Pueblo, Arkansas Valley (Leadville) and Durango. These were operated at about half capacity throughout the year. Lead ore was largely brought in from the Coeur d'Alene district, Idaho, while quite a large tonnage of silicious silver ore was shipped into the State from Cobalt, Canada. The smelting of the latter has given rise to some interesting problems, such as the study and treatment of the cobalt speiss which is formed in the smelting process. It is understood that this work is still in progress, and no information is available. A new addition to the Globe plant was completed last year, viz., an arsenic plant for the treatment of flue dust. The process employed is the usual one of roasting and condensation in flues. Local flue dust is treated, as well as some flue dust that is shipped to the plant from Utah.

A number of independent smelting plants have operated during 1910, some of them leading the usual precarious existence of such institutions, and others apparently prospering as well as the status of the industry will permit. Unfortunately for the industry itself, some of these ventures are ill advised, being the creations of promoters who lack information on the basic principles of the smelting business and proceed along lines which almost necessarily lead to failure. It has been observed also, in some instances, that the greater the hazard the less competent the management and the more sudden the termination of operations. Only by the employment of the most skilful technical talent, combined with the most painstaking preliminary investigation, can such misfortunes be avoided.

The Argo plant of the Boston & Colorado Smelting Company, near Denver, was permanently closed in March, 1910. The company had enjoyed a successful career of 40 years' duration, during a part of which time it operated a secret process of refining which made it independent of the larger corporations which sprang up with the introduction of lead smelting. Argo was operated on a copper basis, and owing to the lack of suitable copper ores in Colorado was forced to secure supplies from other States, often at great cost and little profit. The plant has now been completely dismantled by wreckers, who took charge after a thorough clean-up.

The plant of the Modern Smelting & Refining Company, near Denver, which was blown in during 1909, was closed in May, 1910, after less than a year of operation. During this time the plant was occasionally closed for various reasons and finally abandoned as an unprofitable venture. There have been occasional rumors of a revival of activity, but nothing definite has transpired.

In April last, the smelting plant at Golden, which had been purchased and remodeled by the North American Smelter & Mines Company, was placed in commission. With the exception of a few interruptions this plant has been in steady operation, and the prospects are good for continued success. The company has pursued a sound policy, securing excellent technical and business management, and has endeavored to assure a suitable supply of ore by purchasing good mines. The latest acquisition of the company is the Santiago group of mines in the Clear Creek district. As there are apparently ample funds behind the management it is probable that the plant will be operated for an indefinite period. The matte produced is sold to the Globe plant of the A. S. & R. Company.

Still another matte smelter was put in operation at Alma about the middle of the year. Some of the details of this plant were given in our issue for November, 1910, page 610. It is probable that operations will be irregular this winter owing to the difficulty of getting suitable ore supply.

The Salida smelter of the Ohio & Colorado Smelting & Refining Company has been in operation as usual, although at reduced capacity. This plant is the only custom lead smelter in the State which is not controlled by the A. S. & R. Company. It has the usual standard equipment with the addition of the Dwight-Lloyd sintering machines for roasting and agglomerating fine ore and concentrate. The other smelters use the Huntington-Heberlein system of roasting.

An innovation in smelting furnaces was introduced in Colorado last year, known as the Partridge smelter. The change from the standard type of furnace consists in the use of a low-pressure blast of large volume, preheated by the slag flowing from the furnace. An annular opening between crucible and shaft is substituted for tuyères, and the blast is heated in a chamber into which the slag is discharged. A complete description of the furnace and its operation will be found in our issue for December, 1910, page 671. One of these plants has been erected at Como to treat the ore of a mining company hitherto shipping to custom smelters. Other plants are projected for similiar properties, notably in the San Juan region, where, by reason of isolation, it is difficult to ship ores at a profit which might be concentrated by fire in a simple and efficient furnace like the Partridge.

Zinc smelting in Colorado is in about the same status as in 1909. The plant of the United States Zinc Company at Pueblo has been in operation, with six furnaces and 1440 retorts. The manufacture of zinc dust at this plant was one of the important features of the year. The production of zinc in Colorado has increased greatly during the past year, so that the outlook for this industry is excellent.

On the whole the outlook for the general smelting industry is not particularly attractive, for reasons already given, but it is equally certain that other branches of metallurgy will take the place of smelting and tend to expand the business of ore treatment. The decrease in production of ore suitable for smelting in Colorado is shown by the following figures compiled by Franklin Guiterman, manager for the A. S. & R. Company in Colorado:

	1900.	1909.	Decline per cent.
Gold oz.	1,400,000	1,061,000	24.21
Silver oz.	20,300,000	8,900,000	56.16
Lead lb.	82,137,000	32,360,000	60.60
Copper	No change.		
Zinc	Increasing.		
Value	$50,314,000	$30,196,000	38.55

Chlorination.

The mills of the Portland Gold Mining Company and United States Reduction & Refining Company, both at Colorado City, have continued to use the chlorination process on roasted Cripple Creek ores, following this with cyanidation of the tailings. At the former the chlorine is generated from bleaching powder and sulphuric acid, and at the latter by an electrolytic plant of 100 McDonald cells. The barrel charge at the Portland consists of 20,000 lb. of ore, 300 of acid and 100 of bleach (30 per cent available chlorine). At the other plant the ore charge is the same, with the addition of chlorine solution of suitable strength.

It was expected and earnestly hoped by Colorado metallurgists that the dry chlorination plant of the Western Metals Company, at Georgetown, would be tested during the year. Owing to delays incident to the promotion of a new process the plant has not yet been completed and the initial test is delayed. The process to be used has been described in the technical press,* and is usually referred to as the Malm process. Mr. John L. Malm has made what are expected to be vital improvements on the work of earlier investigators, Swinburne, Ashcroft, Baker and Burwell, whereby the process can be profitably applied to base sulphide ores. The plant at Georgetown will afford an excellent opportunity to test the efficiency of the process, as the Clear Creek district has an abundance of such material.

Cyaniding.

There was an increase in cyaniding in this State during 1910, principally on Cripple Creek ores. It has been predicted from time to time that cyaniding ultimately would supplant chlorination, but as noted above it has not yet fully done so. It is true that chlorination has steadily lost favor with Colorado metallurgists, and it is probable that but for the disinclination to abandon a working plant which represents a considerable investment the present chlorination plants would not be in operation and would be superseded by cyanide works.

Probably the most important event in cyaniding last year was the completion and operation of the Cripple Creek mill of the Portland company. The full details of the process have been kept secret, but it is a direct cyanidation of raw ore, with the addition of a substance or mixture, probably a halogen cyanide and an oxidizing substance. The process was worked out by the metallurgical staff of the company. After coarse crushing the ore is ground in cyanide solution in Chilean mills and concentrated on Wilfley tables. The concentrate is shipped to the old mill at Colorado City. The tailing is classified, the sand being rejected and the slime concentrated on Card tables. The Card concentrate is shipped to the Colorado City mill, and the tailing thickened, agitated and filtered. Zinc dust precipitation according to Merrill's process is used. The plant has a number of new devices, such as the Akins classifiers and Rothwell & Akins agitating tanks, and Portland continuous revolving slime filters. The mill is in steady operation on low grade mine ore, and its successful operation will point the way to the erection of other local mills.

Stratton's Independence mill, which was started in 1909, was in operation last year at about 50 per cent increased capacity This mill is treating dump ore of an average value of $3.60 at a cost of about $1.50 per ton. The ore is crushed and ground in cyanide solution, then concentrated to remove the sulphotellurides, after which the tailing is cyanided.

The Colorado City mills of the Portland, Golden Cycle and United States Companies were in operation throughout the year, although not always at full capacity. The Golden Cycle uses cyanidation exclusively, while the other two use cyanide only on the tailings from the chlorination plants. The Golden Cycle has probably the best roasting plant in the State, comprising a battery of Edwards' roasters, each having a capacity of 125 tons of Cripple Creek ore daily. The roasted ore is ground to 25 mesh in cyanide solution, passed over blankets and then classified in Dorr classifiers. The sand is leached and the slime agitated and filtered in a vacuum system which was newly installed last year Precipitation is on zinc shavings

The only other district in the State where cyaniding has been practised regularly is the San Juan, where the Camp Bird at Ouray and the Liberty Bell at Telluride have been using the process as in the past. There has been a tendency on the part of engineers to extend the use of the cyanide process to other ores and concentrates and during the past year some successful experiments were carried on at Breckenridge and in the Clear Creek district. In connection with this work some new machines were investigated, notably the Bonnot pulverizer and the A. Z. agitator, both of which were found well suited to the work required of them.

The Clancy process of cyaniding was disclosed to the public too late in the year to permit of any tests being made on Colorado ores, but it is certain that the process will be applied to some Cripple Creek ores this year, in an endeavor to test its efficiency. A complete statement of the process will be found in our issue for November, 1910, page 623.

Ore Dressing.

There was probably more activity and new business in this branch of metallurgy than in any other in the State during 1910. The greatest progress was made in the concentration of zinc-lead-iron sulphides, and several new plants were erected and operated. The systems used vary with the nature of the ores, but may be broadly classified into two, viz., those in which roasting is or is not used prior to magnetic separation. Again, the systems employing roasting may use that process either before or after the accompanying wet dressing on reciprocating tables. When roasting is employed low intensity magnetic separators are used, while the high intensity separators are used on raw zinc-iron middlings from wet concentration. The low intensity machines attract the strongly magnetic iron in the roasted mixture, while the high intensity machines attract the weakly magnetic zinc from the raw mixture.

The mills of the American Zinc Extration Company, Leadville; Wilson Mining Company, Robinson; Kokomo Metals Company, Kokomo; Eagle Mining & Milling Company, Red Cliff; United States Zinc Company, Pueblo, and Western Chemical Manufacturing Company, Denver, all use a system of roasting, magnetic separation and wet dressing. With the exception of the Kokomo mill they all use the following general scheme: Crushing, grinding, screening, drying, roasting, magnetic separation of the iron and table concentration of the lead and zinc. At the Kokomo mill the wet dressing comes first, producing lead concentrate, tailing and zinc-iron middling, the last being dried, roasted and magnetically separated.

A difference of opinion exists among metallurgists regarding the relative places of the roasting and wet dressing in the general scheme indicated. Those favoring wet dressing

*West. Chem. & Met., Vol. 5, No. 3; Vol. 6, No. 5.

first and roasting with magnetic separation last argue that they immediately get rid of the tailing and save a lead concentrate and zinc iron middling, the last alone requiring roasting and magnetic treatment. They contend that they thereby avoid unduly loading the drying, roasting and magnetic units with an excess of material that does not require that treatment and consequently reduce the plant required. On the other hand it is contended that slime losses in preliminary wet dressing, and the difficulty in drying the middling, are points against that procedure. Further, that table dressing following roasting is somewat improved owing to the effect which roasting sometimes has of widening the range of specific gravity of the various minerals. It is also claimed that if iron carbonate is present its separation from the zinc is better effected by wet dressing after roasting than before. The two processes have not been in operation long enough to compare their efficiencies or to prove the claims of their adherents.

Several types of roasters are in use at these mills, but the preference is in favor of the multiple superimposed hearth type. A Wilfley vertical furnace was installed at the Kokomo mill, and revolving furnaces at the Leadville plant. At the Western Chemical Manufacturing Company, where sulphuric acid is made from the roaster gases, the furnaces are of the Herreshoff type. The new Wilfley roaster, which was described in our issue for November, 1910, page 646, has not been installed at any plant.

Three types of magnetic separators are used in these mills, viz., the Dings, Cleveland-Knowles and Fairchild. The first two are well known, but the last is a recent device of O. H. Fairchild, superintendent at the Wilson mill, where the machines are in use. There are three sets of magnets of increasing strength arranged transversely to the shaking feed plate. The magnetically separated iron is removed by traveling belts which move around the magnets. In its travel on the belt the iron comes into fields of alternate polarity which cause the particles to change their position and thereby release any mechanically entrained mineral which should not be removed.

Wilfley and Card tables are almost universally used in Colorado, and each has its ardent supporters. At the Leadville mill mentioned above there are some Ford tables in use. In this connection it is interesting to note that during the past summer the Mine & Smelter Supply Company, owning the Wilfley patents, presented its *prima facie* case against the Hendrie & Bolthoff Company, controlling the Card table, in a suit for damages for infringement. The case was heard before a special examiner, but was not finished. Similar suits were instituted against the Deister and Dunham tables.

In the Creede and Clear Creek districts lead-zinc concentration is by wet processes only, as there is but little iron in the ore. Jigs of the Harz type, and Card and Wilfley tables are used. The zinc concentrate from these districts is of excellent quality, ranging from 40 per cent to 55 per cent. The lead is also of high grade, running from 60 per cent to 72 per cent.

The plant of the Empire Zinc Company, at Canon City, has been in operation throughout the year. Raw zinc-iron middling or crude ore is treated at this plant, which is equipped with Wetherill magnetic separators of the high-intensity type. It is understood that the company contemplates the erection of a new plant embodying roasting, magnetic separation and wet dressing. The company has maintained an elaborate testing plant for some time, and has been active in experimental work. The testing plant contains an Elmore unit, Sutton dry table, electrostatic separator and Wilfley roaster.

Tungsten concentration in Boulder County was the principal metallurgical industry of that district last year. The chief difficulty experienced in this work is the tendency of the friable tungsten minerals to slime, thereby causing high losses. The perfection of the Monell slimer last year is said to have reduced these losses materially. The machine is a canvas belt vanner with end motion, and side feed and discharge of tailing. The concentrate is recovered at the end as usual. The principal feature of the machine is its unusual length and large flat concentrating surface on which the mineral particles have ample time to settle with the least possible disturbance in the succeeding washing.

Miscellaneous.

The Colorado School of Mines testing plant was put under construction last fall. This plant, when finished, will be a complete testing mill for ore dressing and metallurgical processes. The fact that the School authorities plan to permit the use of the plant by professional engineers materially widens its field of usefulness. The School will thus perform a service to the State, and the students will have opportunity to witness and assist in many commercial tests on a variety of ores.

The vanadium industry in Colorado has not grown as fast as was expected. The Primos Chemical Company has a mill in operation at Newmire producing vanadate of iron by first roasting the ore with an alkali salt, then leaching and filtering and precipitating the vanadium with ferrous sulphate. Considerable experimental work was done at Boulder last year by Mr. Warren F. Bleecker in an endeavor to improve the process used at present. The results have been gratifying, and our readers will have an opportunity to secure the results of Mr. Bleecker's work by consulting his series of articles which began in our issue for December, 1910.

Portland cement is made in Colorado by two companies, the Ideal and the United States, both operating in Fremont County, at Portland and Concrete, respectively. The shale and limestone used are quarried from beds exposed in the valley of the Arkansas River. Shale and limestone are mixed in the proportion of 2200 lb. limestone to 5800 lb. of shale, making a mixture of about 73 per cent $CaCO_3$ at the mill, or 64 per cent CaO in the finished product. Ball and tube mills are used to grind the mixture preliminary to clinkering, which is done in 120-ft. kilns, using powdered fuel. Fuel consumption is about 140 lb. to 400 lb. of cement. A plaster of Paris plant is also operated by the Ideal Company at Portland. The United States plant is the newer and said to be thoroughly modern.

The discovery of zinc carbonate at Leadville will undoubtedly give metallurgists an opportunity to display their ability in devising treatment for the low-grade ore which cannot be shipped directly to the smelters. Although metallurgical works have lowered the limit on these ores to 20 per cent zinc, there is a vast tonnage that will not run higher than 15 per cent, and there will undoubtedly be a demand for a method of treatment.

The necessity for co-operative work in Colorado metallurgy is becoming more and more apparent. Many districts have an abundance of low-grade ore, which can be mined and treated only by a concerted effort on the part of many small owners. The time has arrived when the mine owner must work out his own metallurgical salvation if his operations are to prove profitable, and if his own property does not of itself warrant a metallurgical plant, he may well consider the advisability of co-operating with his neighbors who are similarly situated. The wisdom of this course has been demonstrated and it should be more widely considered.

Silver Assay.—In addition to being influenced by the temperature of cupellation, the accuracy of the silver assay is also affected by the quantity of litharge used in the fusion. It has been shown that an excess of litharge tends to lower the silver recovered, the litharge probably carrying some of the silver into the slag along with impurities which are dissolved. A flux containing 12 parts each of soda, potash and litharge, 2 of borax glass and 1.1 of flour will give good results if about 80 grams of the same are taken for ½ A.T. of ore.

The Cyanamide Process in the Metallurgy of Gold.*

BY JOHN COLLINS CLANCY.

After the wide publicity given to the Clancy process by the Moore Filter Company, I feel it incumbent upon me to present the following paper for consideration and discussion.

This process is more immediately concerned with the treatment of refractory ores, these ores generally having their values associated with compounds in chemical combination, which are not susceptible to the action of solvents until roasting or some other method of oxidation has disassociated the said compounds and liberated the precious metals. Roasting is by all means the cheapest oxidation process so far known; any attempt to oxidize the base constituents by chemical means is obviously of a very expensive nature, therefore, impracticable.

It is known that, in some cases, profitable extraction of the precious metals from base ores may be obtained, depending on the rapidity of the action of the cyanide upon the finely divided gold in preference to its action upon the base constituents; that is to say, before the base metals are attacked the gold has gone into solution. Sometimes by keeping down the alkalinity of the solution to almost neutral point in "protective" alkalinity a good extraction may be obtained, as the absence of an excess of alkali will protect the metallic sulphides from decomposition and allow the cyanide to work directly upon the precious metals. Of course, these results are only capable of accomplishment when the precious metals are not in chemical combination, unless a solvent for the chemical compounds is present with the treatment solution. The Clancy process to be described in a measure includes the embodiment of these principles.

Preliminary Experiments.

As a preamble, a little history relating to my earlier experiments on refractory ores may not be out of place. The ores of Cripple Creek, Col., may be taken as an example of so-called refractory ore. I need not dwell upon the past or present metallurgical treatment of these ores, but will only state in passing that straight cyanidation on the raw undressed ore yields but a trifle over 60 per cent extraction. It will be apparent, therefore, that a process to extract from about 90 per cent to 95 per cent of the values without roasting or concentration, and at a reasonable cost, would be a boon to the district of Cripple Creek, as well as other districts in different parts of the world. To this task I set myself some years ago, and my improvements may be seen from the different specifications, which show the line of thought and gradations from earlier processes.

The object of my first experiments on Cripple Creek ores was to find a cheap alkaline solvent for the telluride of gold which occurs in these ores, the tellurides existing principally in the form of (AuAg) Te_2, the minerals calaverite and sylvanite being approximately represented by this formula. The minerals calaverite and sylvanite are often found alone, but more frequently associated with pyrite; this close association with the pyrite increases the difficulty of treatment by chemical solutions as well as separation by mechanical means.

I discovered that the alkaline hypochlorites, hypobromites, hypoiodites (NaClO) (NaBrO) (NaIO) dissolved tellurium readily and also attacked the tellurium in the gold telluride crystals, while their calcium salts—the analogues of bleaching powder—were not solvents. Sodium hypochlorite being the cheapest, therefore, there was a possibility that, by crushing the ore fine, the tellurium would be dissolved off and allow of gold dissolution by cyanidation. The equation representing this reaction may take place after the following:

$$Te_2 + 4\,NaClO + 2\,H_2O = 2\,H_2TeO_3 + 4\,NaCl.$$

The tellurous acid so formed would dissolve in the excess of alkali as

$$H_2TeO_3 + 2\,NaOH = Na_2TeO_3 + 2\,H_2O.$$

A preliminary treatment with NaClO, followed by a cyanide treatment on ore crushed to 100 mesh, invariably gave an extraction of from about 80 per cent to 85 per cent of the gold contents, and frequently a higher extraction when the gold telluride in the ore was not closely crystallized with the pyrite.

The preliminary treatment, however, had its drawback, inasmuch as the remnant NaClO left in the pulp after treatment destroyed cyanide unless washed free therefrom. This washing caused extra filtering and meant two sets of solution treatments, and for that reason, together with the alleged high cost of producing NaClO, it was not continued at this time.

My next process was the employment of a soluble persulphate, such, for example, as ammonium persulphate, as a preliminary treatment to dissolve the tellurium contained in the ore. This solvent $(NH_4)_2S_2O_8$ was superior to NaClO, owing to the fact that the iron sulphides did not become oxidized to any appreciable extent while the tellurium was undergoing dissolution.

Another advantage was that the remnant persulphate did not act to destroy the cyanide on subsequent treatment; on the contrary, it hastened dissolution of the gold, after the following equation:

$$4\,KCN + 2\,Au + (NH_4)_2S_2O_8 = 2\,KAu(CN)_2 + (NH_4)SO_4 + K_2SO_4.$$

The high cost of the persulphate, together with the necessity of using two sets of solutions, was the reason for not continuing this method.

I next tried if it was possible to dissolve the tellurium and gold simultaneously by using a mixture of cyanide and persulphate. This scheme was found to work satisfactorily on gold telluride crystals, but when applied to the ore the method was prohibitive on account of the large amount of persulphate required, due principally to the presence and formation in the solution of ferrocyanide, which caused the action of the persulphate to be completely nullified.

The thought then occurred: Could some substance be used to prevent the action of the ferrocyanide upon the persulphate? Reflecting on the behavior of the alkaline hypo-halogen compounds toward KCN, I recalled the weak action exhibited by sodium hypoiodite upon KCN in comparison to that exhibited by sodium hypochlorite and sodium hypobromite; the latter compounds almost immediately converted the KCN into KCNO in alkaline solution—in acid the solution formed cyanogen bromide, cyanogen chloride, respectively.

Guided by this process of thought, the idea of using a soluble iodide, together with the persulphate, in the cyanide solution at once suggested itself. I forthwith tried the effect of potassium iodide in conjunction with persulphate and cyanide solution on gold tellurides, with the result that the tellurides underwent complete dissolution. The nature of the reaction at once explained itself: There being no alkali present in any of these tests, other than the alkali occasioned by the hydrolysis of the cyanide solution, it was simply the persulphate liberating the iodine in presence of the cyanide solution to form cyanogen iodide. The following equations may represent the action shown in two stages:

$$2\,KI + K_2S_2O_8 = 2\,K_2SO_4 + I_2,$$

then

$$I_2 + KCN = ICN + KI.$$

From the study of these reactions I conceived the idea of liberating iodine while the ore was in contact with the cyanide solution by the use of a substance yielding nascent oxygen. Any oxidant might be used which has not a too high velocity reaction, and one which does not unduly increase the alkalinity of the solution so as to prevent the formation and existence of cyanogen iodide in the said solution. Persulphate apparently filled these conditions, as it introduced no free alkali while giving off nascent oxygen, but, on the contrary, neutralized alkali owing to its anxiety to part with one of its sulphions (SO_4) as:

$$K_2S_2O_8 + 2\,KOH = 2\,K_2SO_4 + (OH)_2,$$

*A paper read before the New York section of the American Electrochemical Society.

or we may write the equation in the following manner:

$$2\,KSO_4 + 2\,KOH = 2\,K_2SO_4 + H_2O_2.$$

It will be seen from the above description that the solutions would contain free cyanide together with cyanogen iodide and the oxidizing agent (persulphate), the proportion of cyanogen iodide to cyanide depending upon the speed of the reaction and ratio of persulphate to potassium iodide.

To apply this solution to the treatment of ore and maintain the chemical equilibria necessary for producing cyanogen iodide required very skillful manipulation. For example, the ore had to be made alkaline by applying the necessary protective alkali to the cyanide solution, if excess of alkali was added the persulphate would still liberate iodine, but the iodine so liberated immediately formed alkaline hypoiodite, the hypoiodite formed was rapidly destroyed by the sulphides contained in the ore, thus rapidly using up the oxidizing energy of the oxidizing agent

The amount of alkali to be added depended, firstly, on the acidity of the ore; secondly, on the proportion of persulphate added, the persulphate requiring alkali in proportion to the removal of its SO_4; thirdly, there was influence of time on the rate of progress of the reaction; fourthly, there was the influence of atmospheric oxygen during agitation accelerating the oxidation of sulphides, which developed acidity and required alkali. To control this alkalinity sufficient alkali had to be added, but not enough to destroy the existence of cyanogen iodide; again, the cyanogen iodide formed would, in the presence of alkali and sulphides, form sulphocyanides, representing a direct loss of cyanide.

Nor is this all; when agitation treatment was completed, the solution after leaving the ore preparatory to filtration would drop, i.e., show a greater cyanide consumption than when in contact with the ore. This consumption of cyanide was probably due to the cyanogen iodide formed, together with the remaining persulphate, acting upon the cyanide solution in absence of the retarding influence of the reducing agents in the ore.

When it was necessary to add alkali to the solution in order to secure the proper precipitation in the extractors, a further consumption of cyanide took place after the equation:

$$CNI + 2\,KOH = KCNO + KI.$$

I discovered that this consumption of cyanide could be completely stopped, and the cyanide which had combined to form cyanogen iodide regenerated, by the simple addition of sodium sulphite (Na_2SO_3) and lime according to the equation:

$$CNI + Na_2SO_3 + H_2O = NaCN + NaI + H_2SO_4,$$

while the lime added neutralized the acid produced. The addition of sodium sulphite acted perfectly at this point, but it did not take care of the decomposition of cyanogen iodide to alkaline cyanate produced by the necessary presence of alkali in the ore-treatment process (a measure, of course, not allowable in the treatment tank).

It is obvious that the above process would require a skilled manipulator to obtain results at a reasonable cost. In a word, the process is not foolproof However, if the market price of persulphate would drop to a reasonable figure and a cheap salt were used which would undergo hydrolysis, i.e., give hydroxyl ions in solution to the extent of taking up the acidity produced by the oxidation means employed, then the process would require no more attention than the ordinary straight cyanide process

Ozone as an Oxidizing Agent.

In view of the high cost of persulphate, my attention naturally turned to the use of a cheaper oxidizing agent, and one that would not introduce, as before stated, alkali in the solution. Ozone, therefore, claimed my attention, as previous experiments with ozone gave interesting results. As there were several ozonizing machines on the market at that time, I began to look around for the most economical machine which produced the greatest amount of ozone at the lowest cost. One machine in particular was guaranteed and backed by a reputable, well-known firm to produce from 100 grams to 150 grams of ozone per kw-hour, and figuring the cost of electrical energy at 1 cent per kw-hour, it seemed that I had now struck the right nail on the head as regards a cheap oxidizer.

An ozonizer of the above description was immediately purchased and installed in my laboratory, whereupon I at once set to work to test the action of the ozone on the treatment of ores with cyanide solution containing soluble iodides, using the ozonized air produced by the ozonizer to liberate the iodine from the necessary chemicals while in contact with the ore.

It would take up too much space to give in detail the results of the numerous tests made on different samples of ore. In short, the ozonized air acted as a first-class oxidizing agent and gave excellent results. The only thing against this scheme was that it consumed too much cyanide unless very carefully watched, it being difficult to establish the proper equilibrium necessary not to allow of rapid oxidation to cyanates. The equation representing the action of the ozone upon the iodide was as follows.

$$O_3 + 2\,KI + H_2O = O_2 + I_2 + 2\,KCH,$$

and, of course, the iodine combined with the cyanide to form cyanogen iodide, as already shown in one of the foregoing equations, the excess ozone forming with the cyanide KCNO after the equation

$$O_3 + KCN = KCNO + O_2.$$

The question now was how to prevent this formation of KCNO

Learning from previous tests on ores containing large amounts of reducing agents that the consumption of cyanide was not so great as with ores which did not contain reducing agents, the thought suggested itself to add a reducing agent to the cyanide solution. I knew that potassium sulphocyanide, although in a sense a reducing agent, had no action on straight cyanide treatment, i.e., the atmospheric oxygen was not absorbed by it. Experiments showed that when sulphocyanide was subjected to ozonized air, cyanide was generated according to the equation:

$$KCNS + H_2O + 3\,O_2 = KCN + H_2SO_4$$

The alkali present, of course, neutralized the acid as produced, and the cyanide so formed was not decomposed as long as the sulphocyanide was present.

This action opened up a field for thought, and in the ordinary course of thought I tried the action of ozonized air on sulphocyanide solution containing an iodide. Upon introducing the ozonized air into the vessel containing the sulphocyanide and the iodide solution free iodide was at once liberated. When this experiment was repeated, using part of the same original solution, but with a small addition of alkali, on again passing the ozonized aid through the mixture, the solution immediately assumed the characteristic iodine coloration.

This solution was exceedingly active on gold leaf and on telluride of gold, the presumption being that the solution contained cyanogen iodide and free cyanide. The formation of cyanogen iodide by this means, I presume, may be represented by the equation:

$$KCNS + KI + 4\,O = ICN + K_2SO_4$$

Following up this wealth of discovery, as shown by the above equations, I proceeded with my tests, using the sulphocyanide to prevent the direct formation of cyanate, and was rewarded with most satisfactory results, the consumption of cyanide being very much reduced. However, the amount of cyanide consumption which did take place over and above that consumed by the ore as compared with straight cyanide was probably occasioned by the cyanogen iodide formed being oxidized slowly to cyanate in presence of alkali; the speed in this reaction was not great and probably occurred after the following equation:

$$5\,CNI + 6\,KOH = 5\,KCN + KIO_3 + 2\,I_2 + 3\,H_2O.$$

Potassium hypoiodite (KIO) being formed as an intermediate product, the excess of iodine acting upon more alkali forming

hypoiodite would destroy the KCN formed and eventually become oxidized to KCNO.

Here was a field for the expansion of the process on the large scale, but there is almost always a "but." While the production of ozone was apparently cheap enough as regards the cost of electrical energy, the cost of the machine (installation) to produce enough ozone to treat, say, 1000 tons of ore per day was staggering. The machines required the supervision of trained experts, and for a 1000-ton per day plant a battery of about 500 unit ozonizers would have been required, beside various other mechanical objections too numerous to mention.—"Another hope blasted."

The production of ozone by electrical means is yet in its infancy, and it is only within the last few years that ozonizers have been put on the market to give ozonized air of high concentrations. In the very near future it is probable that ozonizers will be built to give large volumes of ozonized air at high concentration with a small installation of ozonizer units. Meanwhile, I had to look around to find a substitute. How was it to be found? I had already exhausted almost the whole list of economical oxidizers known to chemistry.

Electrolysis.

The employment of the electric current claimed my attention as a means of producing the oxidation necessary while the solution was in contact with the ore. Electrical means for the treatment of ore labors under a stigma, inasmuch as there have been unfavorable criticisms of the use of electrolytic processes, no doubt caused by the numerous failures, among which may be mentioned the electrical precipitation of gold requiring the installation of an enormous plate surface, electrode difficulties and the consequent destruction of the cyanide by the use of the current.

One of the most severe criticisms relates to electrolytic processes in which the direct preciptation of the values from the ore pulp is attempted, the objections probably being due to the scouring of the plates by the circulating ore and the consequent loss of finely divided gold amalgam in the ore pulp.

Much more could be said on this subject, but the Clancy process is not concerned with any electrolytic amalgamating scheme or deposition of the gold on plates or depending upon the dynamical theory of the gold being brought against the cathode electrode and there meeting with a nascent hydrogen or the ore being brought against the anode electrode and meeting its nascent oxygen. The process thus differentiates itself into a method of using the electrical energy to disassociate the chemicals employed and by their agency doing the necessary work.

Electrodes.—Obviously the use of electrolytic methods requires proper anodes. Numerous substances to act as anodes have been tried, such, for example, as lead peroxide, carbon, iron, graphite, etc., but all these substances have been more or less inefficient

Anodes of lead peroxide under the influence of high current densities break down, i.e., disintegrate. Iron when used as an anode is oxidized by nascent oxygen liberated and forms hydrated oxides of iron, and should the cyanide solutions contain halogen salts the corresponding iron halogen compounds are formed. It is needless for me to describe the many difficulties which I have been up against to find a suitable anode. All the common metals, together with different alloys and compounds, were experimented upon to find a substance which would withstand the action of the halogen compound, i.e., some substance that would not combine with either chlorine, bromine or iodine under the action of the current, so as to allow the liberated halogen or the nascent oxygen to do the useful oxidation work in the solution.

Graphite (extruded) stood the electric current fairly well. i. e., makes a good anode while it lasts, but, under the influence of high current density, it disintegrates and cannot be used for any length of time in circulating solutions containing ore in suspension, as it is worn away by the attrition or friction of the ore particles against the said electrodes. Nor is this all; when it is understood that graphite will not stand a much higher density than, say, 10 amp per square foot of surface, it requires no calculation to figure out the amount of electrode surface required on a working scale.

The only metal which would stand up under the electrolysis of cyanide-bearing solutions containing halogen compounds was platinum. But on a commercial scale the employment of platinum could not be entertained for one moment.

After trying out every known electrode which I thought might prove suitable, I found that oxide of iron which had been melted in the electric furnace was the only thing on this side of Jupiter that would stand up under high current densities and not combine with the halogen compound contained in the cyanide solution. The area of anode surface of this material to give the necessary current density is reduced to a fraction of the amount of surface required in the case of graphite.

In general, these melted iron oxide electrodes used as described are particularly suitable for the electrolysis of cyanogen-bearing solutions and present the following advantages over all other anodes, including platinum:

First, they are cheaper, they have an unlimited life in comparison with the other anodes already mentioned. Second, they furnish nascent oxygen free from carbonic acid, which is of great advantage in the electrolysis of cyanide solutions. Third, they do not disintegrate under high current densities and are so hard that they do not wear away by the atrition of the ore pulp in the agitating tank.

Armed with the necessary weapons in the shape of these highly inert refractory electrodes, confidence in my ability based on previous experiments with platinum electrodes, I felt sure that I could do anything in the shape of electrolysis of cyanogen-bearing solutions containing halogen compounds. I could now use high current densities and liberate chlorine, bromine or iodine in the said solutions without worrying about my anode breaking down.

It will be remembered in my earlier experiments that I was confined to the use of iodine or soluble iodide, as no other oxidizer, even ozone, would liberate bromine or chlorine in the alkaline cyanide solution. Taking advantage of these new-found electrodes I experimented with cyanide, sulphocyanide and a soluble bromide, and obtained excellent results on the most refractory ores by keeping the solutions at the neutral point so as to allow of the formation of bromocyanogen while in contact with the ore.

The use of a bromide, as above described, although giving results equivalent to the use of soluble iodide, was more difficult to control owing to the necessity of maintaining the solutions at the neutral point, and required more electrical energy to do the same work as iodide. Again, by keeping the solutions at the neutral point the formation of cyanate was much more rapid, consequently the free cyanide did not coexist very long in presence of the cyanogen bromide, owing to its high speed of reaction. The bromates produced by the oxidation action would accumulate in the solutions and were apparently not reduced to bromides even after passing through the zinc boxes.

In the case of using a soluble iodide any iodates formed were at once reduced by the action of the sulphocyanides. This reaction between sulphocyanide and an iodate is very striking, so much so that if we take a solution of an iodate and add to it a solution of sulphocyanide, on acidifying this solution, immediate liberation of iodine takes place, or, again, if we take a solution of iodate containing sulphocyanide and electrolyze same, iodine is immediately liberated at the anode.

With bromates this is not the case. Bromates are reduced more or less by the nascent hydrogen evolved at the cathode, but this nascent hydrogen has to do other work, in fact, it has no time to look after the complete reduction of bromates, as during electrolysis a thin pellicle of calcium hydrate is produced on the cathode. The formation of this pellicle is occa-

stoned by the presence of calcium salts in the solution. This pellicle scales off, but is immediately reformed, thus more or less preventing the hydrogen gas in its atomic state from coming into contact with electrolyte and will cause a union of the atoms to molecular hydrogen. When the hydrogen has once assumed the form of molecules then its reducing power is at an end. Bromates, therefore, have a chance of partial reduction in the treatment tank.

The advantages possessed by the use of iodine over bromine are the following. Iodine is easily liberated from its compounds at a very low voltage; it does not react violently upon the cyanide solution; it is continuously reduced from its higher oxidation state by the sulphocyanides present in the solutions; it can be liberated from its compound in alkaline solutions, which fact prevents the loss of valuable iodine due to volatilization.

The fact that iodine forms cyanogen iodide in a slightly alkaline solution is of extreme importance in the treatment of ores, as by this fact sufficient free cyanide coexists during the formation of cyanogen iodide. The decomposition of cyanogen iodide to cyanate in the presence of alkali takes place slowly, thus allowing ample time for the precious metal's dissolution.

This method of using cyanide sulphocyanide and a halogen compound in conjunction with the electrolysis of the solution gave excellent results on most of the so-called refractory ores. The cyanide could have been regenerated from the KCNS (i.e., the KCNS which had formed due to the action of the cyanogen iodide upon the sulphides during treatment) but for the presence of the halogen compound.

The reaction $KCNS + 3O + 2KOH = KCN + K_2SO_4 + H_2O$ takes place only to a limited extent. The presence of the halogen salt handicapped this reaction, i.e., it finally became more or less a reversible one after the following equations:

$$KCNS + KI + 2KOH + 4O = KIO + K_2SO_4 + KCN + H_2O,$$

$$KIO + KCN = KCNO + KI,$$

$$KIO + KCN + K_2S = KCNS + KI + K_2O.$$

In a word, the formation of KIO oxidizes the KCN to cyanate, and when regenerating the solution in the presence of ore the KIO acts upon the sulphides in the presence of alkali, producing KCNS.

It will be seen that it is difficult to establish the correct ratios of alkali to obtain an equilibrium to allow of the formation of KCNS and prevent the formation of cyanate. How could this formation of cyanate be prevented? How could the cyanogen-bearing solution be regenerated?

Numerous experiments made with all kinds of additions conducted upon scientific principles with a view to reducing the cyanate to cyanide gave most discouraging results. As far as I am aware, there is no record in technical literature in reference to the regeneration of cyanide from solutions of cyanate. Therefore, I had to launch out into a sea of speculation.

My first experiment was to try the action of the electric current upon a chemically pure solution of potassium cyanate. The action of the current upon straight cyanide (as is well known) results practically in the formation of cyanate. I, therefore, tried the effect of continued effect of electrolysis upon a pure solution of KCNO.

It was not my intention to chase any scientific butterflies, but only the question as to what were the products of electrolysis. I forthwith proceeded with my experiment. On examination of the cathode product NH_3 revealed its presence by its action on the olfactories. At the anode I collected CO_2, the solution meanwhile increasing in alkali. These products for a start were by no means encouraging.

However, as a preliminary to an intended systematic research and to see if there was any possibility of some reduction to cyanide, I withdrew a portion of the liquid from the containing vessel and floated some gold leaf upon the surface of the solution and set it aside for observation, meanwhile continuing electrolysis of the remaining solution. After about 10 minutes this solution became very hot; I was about to throw it out as a spoiled experiment, but, thinking there might be some intermolecular change due to the increased temperature—having in mind among other things Wohler's discovery, viz., conversion of ammonium cyanate into urea—I withdrew a second portion of the solution and floated gold leaf upon its surface, placing it alongside the first experiment.

I watched both solutions carefully. No. 1 experiment, which had already stood 15 minutes, showed no signs of dissolving; No. 2 experiment after 10 minutes surprised me; the gold was surely being dissolved; in 30 minutes it was completely dissolved. No. 1 experiment, after standing all night, showed no signs of dissolution.

Thinking that the reason why No. 1 did not dissolve gold leaf was owing to its not having the same amount of current as No. 2, I set to work and made two experiments under precisely the same conditions, with the exception that one was kept cold by immersion of the containing vessel in a freezing mixture, the other one was allowed to become warm as before. After passing through both the same number of amp-hours of electricity I floated gold leaf on both solutions. On 30 minutes' standing the one that was allowed to become hot dissolved gold leaf completely; the one which was kept cold showed no signs of dissolution even after three days' standing. Platinum electrodes were used in both experiments.

What was the cause of the difference between the electrolyzed hot and cold solutions? Was it the formation of urea? A solution of potassium cyanate containing a small portion of urea I at once electrolyzed, adding a small amount of caustic soda to increase the conductivity; by this means the solution kept at about room temperature. On completion of electrolysis gold leaf was floated upon the surface of this solution and allowed to stand to await results. In about 15 minutes the gold leaf underwent complete dissolution.

From this it would appear that the urea theory was probably correct; or was it the cyanate in conjunction with the urea together with the action of electric current producing cyanide, isopurpurate or some other gold-dissolving compound? Testing with silver nitrate showed an apparently considerable quantity of KCN, but nothing commensurate with its dissolving value on gold leaf.

Cyanamide.

Having made the discovery that urea in conjunction with the cyanate and electrolysis of the solution dissolved gold leaf, the next question was, would any similarly constituted organic compound do the same thing? Urea being an amide compound (carbamide), with the speed of lightning came the thought of cyanamide. I thereupon added a solution of cyanamide (using the calcium cyanamide of commerce, which is soluble to the extent of about 58 per cent to 60 per cent in water) to a cyanate solution, electrolyzed same, treated the solution as before with gold leaf, and dissolution of the gold took place in a few minutes.

With a view to studying this peculiar reaction, I tried the action of electrolysis on a solution of calcium cyanamide; without any admixture other than the addition of a little alkali to increase the conductivity, after electrolyzing for 10 minutes at a fairly high current density the solution dissolved gold leaf in about 15 minutes; this solution also gave a substantial titration with silver nitrate showing probably that cyanide had formed.

Again treating the same solution with the addition of potassium thiosulphate and boiling for the purpose of converting any cyanide present into sulphocyanide, on testing this solution with ferric chloride it gave the characteristic blood-red coloration of the iron sulphocyanide—surely ample verification. But to make it more confirmatory I added a solution of ferrous sulphate to convert any cyanide in the solution into ferrocyanide. On addition of ferric chloride it gave on boiling the characteristic prussian blue.

This satisfied me that some cyanide was formed by the electrolysis of calcum cyanamide, but as to the amount produced

from a given quantity of cyanamide I was in the dark, owing to the peculiar behavior of the titrating solution in presence of organic compounds. It seemed from different experiments made that the production of cyanide by electrolysis of cyanamide solution never rose above three-tenths to four-tenths of a pound KCN per ton of solution.

During all these tests I used solutions of analogous strength to working-scale practice. On referring to Ward's "Dictionary of Chemistry," page 314, line 65, Vol. 2, I found the statement in substance, that cyanamide combines with potassium cyanate to form mono-potassium amidodicyanate of the formula $(CN)_2 NH_2 OK$. Reflecting on this reaction I thought probably that, as the cyanide was formed by the electrolysis of the cyanamide, it was oxidized by the current to cyanate, the cyanate then acting upon the unaltered cyanamide to form potassium amidodicyanate, and potassium amidodicyanate when electrolyzed forms a powerful gold solvent, although it does not give any appreciable titration with silver nitrate.

It will be, I trust, appreciated that to go into the discussion of these reactions would not only require an enormous amount of space, but prove too severe a tax upon my time. Suffice it for the present to say that I have a number of notebooks filled with the most interesting data in regard to these reactions, showing how they branch off and become diversified. I, therefore, propose later on to publish the results of the different experiments and give the theory relating to the data of my notebooks.

To go into practical work is more to the point of this article. However, before leaving the theory, which is always the necessary scaffolding for building up an edifice, I may state that when a solution of calcium cyanamide is mixed with a solution of alkaline ferrocyanide and allowed to stand for a few hours, and even after weeks' standing, it becomes an active solvent for gold, even without the aid of electrolysis, and when applied to the treatment of ores amenable to straight cyanidation gives results equivalent to the simple cyanide treatment even in very dilute solutions.

Further this process can be used on ores which have already been treated by the cyanide process; that is to say, on the residues commonly known as dumps. There exists in these dumps a large proportion of prussian blue, which, when treated with alkali, becomes in substance potassium ferro and ferricyanide or soluble prussiates.

This opens up a cheap means of treating ores amenable to the ordinary cyanide process as well as ores—residues—which have already been treated by the cyanide solution. That is to say, ores in which the precious metals have not been wholly extracted, and would not pay for retreatment by the ordinary cyanide process on account of the cost of cyanide.

The following is an example of using this process upon ore amenable to cyanide treatment:

Two thousand pounds of water containing 1 lb. of calcium cyanamide, 1 lb. of alkaline ferrocyanide, 1 lb. of lime. The ore is subjected to this solution in the ordinary way, say, in proportion of two parts of solution to one part of ore, for a period of, say, 8 to 10 hours, or until extraction is complete.

The following is an example of using the process upon ore which has already been treated by the cyanide process and exposed to atmospheric oxygen which occasions the formation of prussian blue and other ferrocyanogen compounds.

This ore when treated with a solution containing 1 lb. of cyanamide, 1 lb. to 5 lb. of lime (the amount of lime, of course, depending upon the acidity of the ore) in 2000 lb. of water gives results equivalent to the use of straight cyanide solution when used in the proportion of two or three parts of solution to one part of ore.

Again, if this mixture is electrolyzed the solution of the gold is extremely rapid. Calcium cyanamide mixed with alkaline sulphocyanide, electrolyzed, immediately becomes cyanide and dissolves gold rapidly. To show the action of another amide compound, for example, guanidine carbonate mixed with potassium cyanate in conjunction with electrolysis of the solution dissolves gold leaf in less than 10 minutes. I might go on here and cite a whole list of amidogen compounds in conjunction with cyanate solution if space would permit, and I have no doubt this would be interesting to those following this subject.

In the midst of this work on cyanogen-bearing materials the thought occurred to try the combination of calcium cyanamide and iodine. I forthwith made a solution of calcium cyanamide, adding a solution of iodine to see if this combination would dissolve tellurium, and was awarded by finding it to be an excellent solvent. I next tried gold leaf on the same combination and had the satisfaction of seeing the gold undergo dissolution in a short time—a scum of calcium carbonate forms on the surface, preventing more rapid dissolution. From this I deduced that the addition of iodine formed cyanamidogen iodide.

I am unable to find any reference to this compound in chemical literature which I have read, and I, therefore, take the liberty of calling it by the above name and further presume the formula to be CN_2I_2. I next tried the action of cyanogen iodide upon a solution of calcium cyanamide and knowing that cyanogen iodide would be destroyed by an excess of alkali, anticipating that this combination woulld dissolve telluride of gold. Upon applying this solution to tellurium, telluride of gold, these substances at once dissolved, showing that the dissolution was probably due to cyanamidogen iodide, and I again presume the reaction to be in accordance with the formula

$$2\,ICN + CaCN_2 = Ca(CN)_2 + I_2CN_2.$$

Practice of Process.

I will now describe the general method of using the Clancy process on the working scale. The ore is crushed by stamps, rolls, ball mills or any other efficient form of preliminary grinding mills. The degree of fineness necessary for the process being about 100 mesh, this degree of fineness is probably most economically accomplished by the use of tube mills.

The ore is crushed in the cyanide solution containing calcium cyanamide, sulphocyanide and the halogen salts; it is, therefore, under the influence of straight cyanide treatment practically after leaving the rock breakers until it reaches the agitation tank. In the agitation tank it meets with electrolysis, which acts upon the cyanide containing the additional chemicals in solution, forming powerful solvents for the precious metals as already described.

Before describing the treatment solution the manner of dissolving the cyanamide should be known. Calcium cyanamide of commerce comes as a black powder and is about from 58 per cent to 65 per cent soluble in water. It is necessary, therefore, to dissolve the cyanamide in a separate tank and filter from its insoluble residue. A small air-agitating tank is admirably suited for this purpose, which at the same time will act as a cyanamide storage tank. The cyanamide solution may be made as highly saturated as desired and the calculated quantity drawn off when required and added to the cyanogen-bearing solution.

The treatment solution is made up to 2000 lb. of water containing 1 lb. of cyanide, 2 lb. of alkaline sulphocyanide, 2 lb. of calcium cyanamide, ¼ lb. of alkaline iodide, 20 lb. commercial sodium chloride.

I use, after the rock breakers, say, for example, crushing rolls. The product leaving the rolls about 12 mesh is fed into the tube mill and converted into a pulp by feeding the mill with the treatment solution and ore in the proportion of two or three parts of solution to one part of ore.

The discharged pulp after separation of the over size is transferred to the agitation tank to undergo electrical treatment. If it is thought necessary to remove the sulphides before, after or during the treatment the following method presents an ideal scheme:

Let solution containing finely divided ore in suspension be contained in the well-known cone-shaped tank and agitated in

the proportion of two of solution to one of ore, or in the proportion of three of solution to one of ore; if the agitation is then stopped for a few minutes the finely divided sulphide particles settle to the bottom of the cone and by simply opening the discharge valve at the cone apex the sulphide may be completely drawn off together with a small proportion of the non-sulphide pulp. The sulphide product may be run over blankets or similar contrivances and the finely divided concentrate collected. The excess of pulp solution is returned to the agitation tank for treatment.

Here is a means to eliminate the use of concentrating tables and obtain a product of very high value in a very small bulk. Again, the pulp being in a very finely divided state the pyrite or sulphide portion is not accompanied with quartz or gangue —therefore, a clean high-grade concentrate—which result is not capable of accomplishment by the use of concentration tables without the employment of a large quantity of solution with its attendant expense.

The pulp now in the agitating tank carries the correct alkalinity, this being previously established in the tube mill by adding lime so as to contain from 1/10 to 2/10 of a pound "protective" alkalinity per ton of solution.

The conductivity of the pulp is adjusted by adding common salt until the required voltage is obtained. Twenty pounds of salt per ton of solution, as already stated, will invariably decrease the resistance of the pulp so that the voltmeter will register about from 5 volts to 6 volts. In the majority of cases a current of about 50 amp per ton of ore is adequate. It will be easily seen that the cost for electrical energy is not by any means prohibitive.

With iron oxide electrodes it is possible to obtain a current density considerably over 50 amp per square foot of anode surface so that one electrode 3 ft. in length by 3 in. in diameter will be sufficient for the treatment of from 3 tons to 4 tons of ore In other words, approximately thirty of these iron oxide electrodes would be required for the treatment of 100 tons of ore per day.

If the treatment tank is constructed of iron the tank itself may be used as the cathode. This arrangement would, of course, decrease considerably the cost of installation. The electric generator is the chief item of cost, but a low-voltage generator, say, a 10-volt machine, capable of giving the necessary amperage can be obtained at any of the electrical warehouses.

It is obvious, therefore, that the process may be applied to any existing fine grinding plant provided with agitating tanks. All that is necessary is simply to introduce the electrodes into the circulating ore pulp containing the necessary chemicals and switch on the current. It is essential in every case to maintain the alkalinity, i. e., protective alkalinity at about 1/10 lb. alkali per ton of solution so as to allow of the formation of cyanogen iodide cyanamidogen iodide. About eight hours' treatment under electrolysis usually being sufficient to obtain the necessary extraction

Regeneration of the Cyanide.—After the eight hours' treatment with the current the pulp solution is brought up to about 1 lb. per ton of protective alkalinity by adding caustic soda and the cyanide contents regenerated up to about 5/10 lb. or 6/10 lb. cyanide per ton of solution. The regeneration of the cyanide is then accomplished simply by giving the pulp two hours more current It will be understood that the reason for adding the extra alkali is that cyanide regeneration cannot take place in the presence of a halogen compound unless the solution containing sulphides, sulphocyanides and cyanamide is made alkaline

It will be seen that the whole value of the process depends upon the recovery of the halogen compound. While I have described in the examples a proportion of two parts of solution to one part of ore a proportion of three parts of solution to one part of ore may be used with advantage—that is to say, by using three parts of solution to one part ore a much smaller amount of alkaline halide may be used per ton of solution, thus giving the same ratio of halide salt per ton of ore as in the two of solution to one of ore pulp and consequently a less proportion of soluble halide to be displaced by the water wash in the final slimes cake.

Costs.—In this incomplete description of the process the use of chemicals and current have been dealt with, but no mention of costs has been made. I will, therefore, take the following solution to represent the typical working solution, 2000 lb. of water containing 1 lb. of cyanide, 2 lb. of sulphocyanide, 2 lb of calcium cyanamide and ¼ lb. alkaline iodide. This appears a formidable mixture when looked at cursorily, but on analysis it does not work out beyond the limits of economic treatment

For example:

1 lb. of cyanide	18 cents.
2 lb. of cyanamide	6 "
2 lb. of alkaline sulphocyanide	12 "
¼ lb. of alkaline iodide	35 "
Total	71 cents.

This would not represent the total cost of one ton of solution, for, notwithstanding the effect of electrolysis, practically all the haloid salt or salts previously added, together with the sulphocyanide, will be found impaired at the end of the operation, the cyanide and cyanamide alone suffering the necessary decomposition. It is clear, therefore, that no matter what the proportion of solution to ore only the consumption of cyanide and cyanamide per ton of ore is to be taken into account. The amount of cyanide consumption on the ore in presence of cyanamide works out at about 1 lb. of cyanide per ton of ore treated. This consumption of cyanide is regenerated at the expense of 3 cents for cyanamide and at the very outside 3 cents for current (figuring current at 1 cent per kw-hour), making a total cost of 6 cents per ton of ore.

Added to the above cost is the cost of the electrical energy necessary for the electrolysis of the ore pulp. The cost of electrical energy for this purpose works out at about 10 cents per ton of ore treated. This added to the cost for cyanogen-bearing material and regeneration would make a total of 16 cents per ton of ore. These figures would represent the total cost provided that all the solutions were recovered without mechanical loss. From this it is evident that the recovery of the solutions for reuse is a matter of vital importance to this process. The mechanical recovery of the solutions is therefore entirely dependent upon the efficiency of the filter employed.

The Moore filter eminently fulfils the requirements of the process for the recovery of the solution inasmuch as it gives perfect uniformity of cake both in thickness and porosity, which means perfect resistance, and perfect resistance guarantees perfect displacement. In fact, the business combination of the Moore filter with the Clancy process was originally brought about not from any arbitrary or usual business considerations, but because I, after the most rigid examination of all existing filter processes, learned in my demonstrations that this type of filter was the only one that could be depended on to recover practically all of the solutions.

This filter process is too well known to describe it here minutely. Suffice it to say, when the final step in the cycle of treatment is reached—that is, when the cake has been washed with barren solutions—the moisture (containing soluble salts) saturating the cake at this juncture may be completely water washed by giving it the requisite amount of water for displacement. The necessary amount of water for displacement is readily seen without calculation by the diminution of the water level in the wash tank. Further, this may be adjusted to a nicety at the will of the operator, obtaining results not capable of accomplishment by any other known filter. It has been necessary for me to mention the unique points of this filter so as to show how the solutions can be recovered with a minimum of mechanical loss and with a minimum of water

wash. In a properly constructed Moore filter, type A, the loss of solution under proper manipulation should not exceed 10 per cent of the total solution.

It should be understood that the above figures are based on the treatment of rebellious or refractory ores and that they would in all probability be much reduced when dealing with non-rebellious ores.

New York City.

Metallurgy in British Columbia in 1910.

BY E. JACOBS.

The most prominent features in metallurgy in British Columbia are those in connection with the smelting of lead and copper ores. Of nearly a dozen smelteries—one zinc, three lead and the remainder copper—only four are being operated at the present time, namely that of the Consolidated Mining & Smelting Company of Canada, Ltd., at Trail, smelting both lead and copper ores, and the respective copper smelteries of the Granby Consolidated Mining, Smelting & Power Company, Ltd., at Grand Forks; the British Columbia Copper Company, Ltd., at Greenwood (both in the Boundary district); and the Tyee Copper Company, Ltd., on Vancouver Island. There does not appear to be any immediate prospect of other smelting works being operated in the province.

Stamp mills, mostly for gold-quartz ores, have been erected and equipped in various parts of the province, including one with 80 stamps and cyanide plant, at Ymir; one with 46 stamps and cyanide plant at Fairview, Osoyoos mining division; one with 40 stamps and cyanide plant at Hedley; two with 20 stamps each at the Queen mine, Sheep Creek, and the Granite-Poorman mine, respectively, both mines being in the Nelson mining division; one with 15 stamps at the Jewel mine Boundary district; several with 10 stamps each, of which only that at the Second Relief mine, Nelson division, has been worked lately, and some with fewer stamps, chief among these last being that with four stamps at the Nugget mine, Sheep Creek.

Of more than a score of concentrating mills, all but two of which produced nearly $80,000 worth of gold in 1910, which have been equipped for treating silver-lead ores, and several of these for saving zinc as well, less than one-half have been operated during the year, and only two or three the year through.

Stamp Milling and Cyaniding.

The Hedley Gold Mining Company's 40-stamp mill at Hedley, Similkameen, is the only one meriting more than pasing notice at this time. The Ymir and Fairview plants have long been idle; the Granite Poorman, Queen and several smaller mills crush the ore and save most of the gold on the amalgamating tables, and send concentrates to the smeltery to recover that not lost in the tailing. The Jewel mill is provided with a Nichols slimer, but has not yet been run expect experimentally since its recent completion. Passing over all others some attention may be given to the Hedley plant.

Hedley Gold Mining Company's 40-Stamp Mill.—The Hedley mill was erected and for several years operated by the Daly Reduction Company prior to its acquirement last year by the Hedley Gold Mining Company. To date its aggregate of production has been of a value of between $2,500,000 and $2,700,000 from 231,000 tons of ore. A recently published return showed an average assay value of $12.18 for 29,385 tons of ore, and an average recovery of $11.25 per ton, the period covered having been eight months, January-August, of 1910.

The following description has been supplied: The stamps in the four 10-stamp batteries are 1050 lb. each. Formerly they dropped 6 in. at 106 per minute. Last summer changes were made giving a 7¼ in. drop and 99 per minute, one result being a considerable increase in the crushing capacity without requiring the 20-mesh screens to be changed. During recent months new equipment has been put in, the completion of which alters the milling practice to the following: Stamps crush to only 16 mesh, the pulp is classified by eight Bunker Hill screens, the coarse product being concentrated on eight corrugated belt vanners, and the vanner tailing pulverized to 100 mesh in a 100-ton Gates tube mill having Montana-Tonopah lining. The tube mill product unites with the fine from the Bunker Hill screens (running less than 60 mesh), and after being reground passes to classifiers and hydraulic sizers, the coarse from the latter is concentrated on 16 smooth belt vanners, the fine from the sizing passing to 10 Deister tables. The middling from these tables is concentrated over two similar tables. The tailing from the smooth belt machines passes to the sand vats, and that from the Deister tables to the slime vats, this being the method of separating sand from slime. None of the sand reaches the leaching vats coarser than 60 mesh. This new method provides for the single treatment of the sand, the proportion of which is but 25 per cent of the whole. The slime is collected in four 200-ton settlers and pumped thence into six 200-ton agitating tanks in which mechanical agitators are used. The gold solution is decanted from the agitating tanks and treated by two Merrill precipitation presses, in which zinc dust is used. The slime residue in the agitating tanks, remaining after decantation, passes to two Oliver filter presses, the solution to the precipitation presses, and the caked slime to the dump. The first cyanide being introduced into the sand vats and agitating tanks, there is no crushing in cyanide solution. The consumption of cyanide per ton of sand and slime treated amounts to ½ lb. and costs 10 cents per ton. The concentration amounts to 200 tons per month; its base is arsenopyrite, and it runs high in gold. It has been sent to the smeltery at Everett, Wash. The foregoing information is supplied by the superintendent, Gomer P. Jones, and is practically the same as he has presented elsewhere.

Charles Camsell, of the Canadian Geological Survey, in an official report, says: "As the ore is an auriferous arsenopyrite, gold is virtually the only product, and an extraction of about 92 per cent of the total value of the ore is made from amalgamation, cyanidation and smelting. A small percentage of copper, silver and some platinum is known to occur in the ores, and assays show a variable proportion of cobalt, nickel, lead and bismuth. The arsenic is a waste product, so far as the mines are concerned, and no credit is given for it by the smeltery."

About 47,000 tons of ore were milled in 1910, and from this gold to the value of approximately $516,000 was recovered. Power plant and new mill equipment put in during the year cost $115,000.

Silver-Lead and Zinc Concentration.

The Consolidated Mining and Smelting Company's concentrating mill at its St. Eugene mine, Moyie, East Kootenay, is the largest concentrator operating on lead ores in British Columbia. During seven years, 1904-1910, it has treated approximately 1,000,000 tons of St. Eugene ore, from which about 185,000 tons of lead-silver concentrate have been produced, of a total value of $10,250,000. The St. Eugene ore is of a silicious nature, lending itself readily to concentration, which has been about six to one, the concentrate averaging 66 per cent lead. The mill flow sheets show the following: Farrel crusher, picking belt, Blake crushers, rolls, Vezin sampler, elevators, trommels, bull jigs, trommels, rolls, three and four compartment jigs, Huntington mills, Callow screens, sloughing-off tank, Callow tanks, Wilfley tables and Frue vanners. Final middlings from the Wilfleys, containing 20 per cent zinc and 4 per cent lead, are stored for further treatment for zinc. The lead concentrate is shipped to the company smeltery at Trail. The capacity of the mill is 400 to 600 tons daily.

During 1910 an ore-testing plant was practically all put in

It comprises 7 by 9 Blake crusher, set of 15 by 25 rolls, automatic Vezin sampler, three trommel lines, two elevators, four-compartment Richards jig, two Hodge jigs, one each No. 4 and No. 5 Wilfley tables, Wilfley slimer, Overstrom table, Frue vanner, Behrend dry separator, Dings electric magnetic separator, four screens (Callow style), flotation tank, settling tanks, classifiers, etc. A Wetherill separator is being installed, and the putting in of a unit of the Murex magnetic process is contemplated. In addition, the mill is equipped for making cyanide and amalgamation tests. With the exception of these last-mentioned equipments, the mill is designed to make tests on large tonnages of ore, practically all the machinery and plant in it being of the standard sizes used in mills.

A concentrator of 200 tons daily capacity was running at the Blue Bell Mine, Anisworth division, during 1909 and part of 1910. It was designed to treat a large body of ore—more than 300,000 tons—the sampling of which showed an average content of 10.6 per cent lead, 11.7 per cent zinc, and 3.27 oz. silver per ton. This ore was estimated to carry: Quartz and other gangue, 30 per cent; iron sulphides (chiefly pyrrhotite), 35 per cent; zinc blende, 22 per cent; galena, 13 per cent. The products were to be, respectively, lead, zinc and iron concentrates. After leaving crushers and rolls, the ore was elevated to a trommel line, passed thence to two and five compartment jigs and Huntington and Ferraris mills, and the lead pulp thence to Callow screens and tanks and to No. 5 Wilfley tables. The intended separation of the zinc from the iron was not generally successful, so a marketable zinc product did not result. Between 70,000 and 80,000 tons of ore have been milled and more than 6000 tons of concentrate produced, the silver and lead contents of which, however, fell short of the proportions indicated by the above-mentioned sampling.

Of the several mills at Whitewater, Sandon and near Silverton, respectively, that have for several years produced both silver-lead and silver-zinc concentrate, only the last will have notice. In an official report it is thus briefly described: "The Wakefield mill is a well arranged and well ordered plant driven by water power. Jigs operating on 16 mm., 12 mm., and 6 mm. material produce a lead concentrate only, the middlings being recrushed. Jigs operating on 4 mm. material produce a lead and zinc concentrate, the middlings going to a Huntington mill. All smaller sizes are classified, and go to seven Wilfley tables to produce both lead and zinc concentrates. The first Wilfley also makes middlings, which are recrushed. This mill has been operated under lease by the Van Roi Mining Company (Ltd.), of London, England, but its lease having expired, the company is now erecting and equipping its own mill in the same neighborhood.

Concentration of copper ores has been in progress at the Le Roi No. 2 Company's mill, Rossland, and that of the Britannia Mining and Smelting Company on the coast in New Westminster Division. The Le Roi No. 2 mill has a capacity of 80 to 100 tons a day, but usually only half that quantity is put through it. The mill plant includes three Blake crushers, two 6-ft. Chilian (Trent) mills, and four Wilfley tables operated by electric motors. The ore is hand picked; the first-class ore is shipped to the Trail smeltery, while the second-class, constituting about 35 per cent of the whole, is milled. The latter averages 0.4 per cent copper and 0.085 oz. gold per ton, and yields a concentrate containing about an ounce of gold per ton and 2 per cent copper, with an extraction of 75 per cent of the gold and 20 per cent of the copper.

The machinery and plant put in its mill several years ago by the Britannia Company included forty Hartz jigs, Hancock and Wall jigs, Blake crushers, Gates rolls, Huntington, Chilian and Monadnock mills, Overstrom, Wilfley, and Cammett tables (36 in all); 40 Johnston and Frue vanners, Sperry slimers, Richards classifiers, trommels, sand pumps, etc. Some time ago production was maintained at between 400 and 500 tons per day, but latterly the plant has been operated only intermittently, and then chiefly for the purpose of experimenting. In concentrating Britannia ores the result aimed at was the removal of the excess of silica, in order to make a desirable product for smelting with a minimum of copper loss, rather than to concentrate to a high grade of copper. The extremely hard matrix of much of the ore limits the application of concentration. Experience proved that the copper losses in the slimes, resulting from fine crushing, were too great, and that a large part of the ores contained mineral that could easily be separated from its gangue without fine crushing. The practice for some time was treatment which gave a concentrate about neutral as to its iron and silica contents, and from the picking belt a shipping ore carrying a large excess of silica. A modification adopted was to take from the picking belt both the high grade neutral shipping ore (to go to the smeltery crude) and the waste, and to leave the remainder to be crushed for concentration by jigs and on tables.

Smelting Ores Containing Copper.

Granby Company's Smeltery.—The Granby Company's smeltery at Grand Forks is stated to be the largest copper reduction works in the British Empire and among the biggest in the world, second only to the great Washoe works at Anaconda, Mont. It has eight rectangular water-jacketed blast furnaces, six being 44 by 266 in. and two 48 by 260 in. at tuyeres, depth 15 ft. 8 in.; capacity 4000 to 4500 tons of ore per day; 12 Connersville blowers, with a total air capacity of 239,000 cu. ft.; specially designed mechanical charging system; slag haulage by 14-ton steam locomotives and 44-cu. ft. slag cars; three converter stands, 84 by 126 in., operated by electricity, and one stand 72 by 100 in. for which hydraulic power is used, converter capacity being 36,000,000 pounds of copper per annum; three blowing engines, total capacity 19,700 cu. ft. of air per minute, and much accessory plant and machinery.

Conditions at the Granby Company's works are different to those obtaining at other copper smelteries outside the Boundary district of British Columbia in that the Granby Company has to treat an ore giving a very low percentage of sulphur on the charge—as low as 2 per cent. On the other hand, the ore contains silica, iron and lime in such favorable proportions that no barren flux, neither iron nor lime, is required. If it were necessary to use an iron flux in smelting Boundary district copper ores, it would not be practicable to mine and treat them at a profit unless the price of copper was much higher than it usually is, for the iron ore obtainable in the district in considerable quantity does not contain any marketable value. The slag from the Granby furnaces runs from 45 to 48 per cent silica all the time, while occasionally it has contained as high as 52 per cent, which has been the maximum reached. The ore is smelted as it comes from the mine. As a rule, it ranges from 40 to 48 per cent silica. Smelteries in other parts generally have ores running higher in sulphur than they require, but they have the advantage of a low silica content in the ore. It will be seen, therefore, that, as already stated, conditions under which the Granby Company's furnaces are ordinarily operated are quite different to those attending the reduction of copper ores elsewhere than in the Boundary district.

The low average of Granby ores makes it imperative that labor costs shall be kept down as much as possible, consequently wherever it is practicable to use them, mechanical devices are substituted for the labor of men. This is especially the case in feeding the furnaces, there being no mixing of the charge or other handling of materials between the ore and coke bins and the furnaces. Cars pushed by electric locomotives receive the ore and coke direct from the storage bins and dump them into the furnaces, the mechanical arrangements being such as to admit of this being done quickly and effectively. The company's engineers have devised many ap-

pliances for labor saving, so that economy in working methods is general throughout both mines and smeltery.

It is probable that in the near future changes will be made in the smeltering practice that will admit of a further saving being made in cost of treating Granby ores. The company has lately secured under option of purchase mines that it is believed will yield largely heavy sulphide ores. Heretofore it has been, and still is, the practice at the company's smeltery to produce a 35 to 40 per cent copper matte at first smelting, which involves a loss in the slag of about 5 lb. of copper to the ton of ore. With the sulphide ores above referred to as an aid to the proposed change, it is believed a saving will be effected, and as a consequence more profit be made out of the ores from the company's big mines at Phoenix, B. C. The ore will be smelted to a 10 per cent matte, which will be regraded to a 45 per cent matte for converting. It is thought that not only will the cost of converting to blister copper be less than at present, but by utilizing as fuel the heavy excess of iron and sulphur in the sulphide ores the percentage of coke required in the charge will be reduced. It is expected, too, that the copper loss in the slag will be less by 1½ to 2 lb. per ton of ore, which of itself would mean an appreciably large addition to the profit to be made out of ores from the company's mines at Phoenix. Mr. Wakely A. Williams, superintendent of the smeltery, has been with the Granby Company ten years, during which period he has effected many economies in connection with the handling and treatment of ores received at the works.

British Columbia Copper Company's Smelteries.—During 1910 the British Columbia Copper Company increased the total blast furnace capacity of its smeltery at Greenwood, Boundary district, by one-third, thereby bringing its maximum treatment capacity up to about 2600 tons per diem. This was done by increasing the hearth area of two of the three furnaces by 50 per cent. Previously all three furnaces were 48 by 240 in. at the tuyeres, and their approximate average total capacity had been about 1800 tons daily, with a maximum of nearly 2000 tons. Now they will average between 2400 and 2500 tons per diem.

This increase in smelting capacity has necessitated a corresponding increase in the plant for feeding the furnaces and taking away the molten slag; also an extension of the crane run at one end of the converter building. For slag hauling a larger locomotive, capable of handling two 25-ton slag cars at a time instead of one, as in the past, has been put in. Heretofore there have been in use two 15-ton Baldwin-Westinghouse electric locomotives for slag hauling and three 7½-ton locomotives for furnace charging. An additional charging locomotive has been put in to meet the increased capacity. The slag cars are 25-ton ladle cars, side dumping, and each is equipped with an electric motor having worm gear for tilting the car to dump its contents. The company was the pioneer in using this style of car for slag dumping. The design has since been adopted by the Canadian Copper Company at Copper Cliff, Ontario, and probably a dozen other smelting works, the latest having been the International and the Mason Valley companies in Utah and Nevada.

In the copper converting department of the works at Greenwood there are two converter stands with 84 by 126 2-in. horizontal shells, these taking matte of 45 to 55 per cent copper tenor and producing blister copper 99.3 per cent pure; also containing 20 to 30 oz. silver and 5 to 15 oz. gold per ton. This product is sent to New Jersey for refining. The stands are tilted by hydraulic accumulators, and the shells handled by a 40-ton, four-motor traveling crane. Two more converter shells have recently been added, making a total equipment of seven.

Electric power, transmitted from Bonnington Falls, distant more than eighty miles, is used in the works, in which there are installed motors having a total capacity of about 2000 hp. Among the motors are three of 300 hp, each belted to one of three large Connersville blowers, which supply the blast to the furnaces.

The company obtains the greater part of its ore supply from its own mines and those of the New Dominion Copper Company, which it controls, and it endeavors to maintain an average monthly output as follows: From the Mother Lode, 36,000 tons; Rawhide (New Dominion), 20,000 tons; Wellington Group, 3500 tons; Napoleon at (Boyd's Wash.), 2500 tons. Mother Lode and Rawhide are typical Boundary district copper ores—as they are quite low in marketable metals; Wellington group ore is chiefly oxidized, and having little value other than gold; of the Napoleon ore, the sulphide goes to the smeltery, where it serves as a pyrrhotite flex to reduce the tenor of the copper matte, while the oxidized ore is to be treated in a mill in course of erection near the mine. Provision is being made for increasing the ore supply from the company's mines, and thus render the smeltery independent of custom ores, if these be not obtainable to advantage. The Rawhide output is to be increased to 30,000 tons a month, while 3000 tons will be obtained monthly from the Lone Star, situated just south of the International Boundary line and eight miles from the works. The Lone Star mine is being connected with the Canadian Pacific Railway by an aerial tramway five miles in length; it has an available reserve of 300,000 tons of gold-copper ore of a higher average copper tenor than that from the company's other mines, besides being a good matte maker.

Coke is obtained from southwest Alberta, the railway distance between the colliery and smeltery being 370 miles. With three blast furnaces running, the consumption is 8000 to 9000 tons a month. A reserve of 10,000 to 12,000 tons is kept as an emergency supply in case of interruption in the regular receipt of coke from the colliery.

The approximate figures of production during 1910 are as follows: Material smelted, 456,000 tons. Contents: Gold, 25,640 oz.; silver, 85,900 oz.; copper, 7,351,000 lb. Included in the ore receipts were the following: From the Mother Lode Mine, 352,000 tons; Oro Denoro, 11,473 tons; Wellington Group, 19,200 tons, and Rawhide, 54,400 tons. Mr. J. E. McAllister is general manager, and the number of men employed is 500 to 540, of which total 118 is the normal force at the smeltery.

Tyee Copper Company.—This company's smeltery is situated at Ladysmith, Oyster Harbor, Vancouver Island. Custom ores, chiefly from various parts of the Coast district of British Columbia, southern Yukon, and southern Alaska, have, during recent years, constituted the chief part of the total supply obtained.

At a general meeting of shareholders held recently in London, England, the chairman said in part: "During the year the effects of the low price of copper were to seriously hamper the company's business, mine owners having no inducement to proceed with development, to ship ore freely or to open new mines. Nevertheless the company received 21 per cent more ore than in the previous year. The quantity received, however, had only sufficed to keep the furnaces running 188 days, but as the standing charges were the same whether the furnaces were fully or only partially employed the financial results afforded hope for improvement. Between May 1 and Aug. 1, 1910, the ore received was 19½ per cent in excess of the quantity for the corresponding period of 1909. The manager had reported from British Columbia that negotiations for the acquisition of an important group of properties had been almost closed." Since then it has transpired that the Cornell Mine, one of the Van Anda Group on Texada Island, B. C., has been leased by this company, and that the question of also taking over other property in the group is under consideration. The grade of the ore from the Cornell is shown in the following figures: Production in 1909, 10,178 tons; average assay value, copper (wet), 3.78 per cent; gold, 0.297

oz., and silver, 1.38 oz. per ton. During seven months of 1910 the tonnage was 4501 tons, and the average assay value: Copper, 4.47 per cent; gold, 0.407 oz., and silver, 1.73 oz. per ton. Transportation from the mine to the smeltery is by water, and the trip occupies but a few hours.

Lead Smelting and Refining.

As the Consolidated Mining and Smelting Company, of Canada (Ltd.), smelts both lead and copper ores, and also refines lead, brief notice of all its operations will be put under one subhead. Much of the information here given has been published before, but the present data have been specially revised and corrected by officers of the company.

The company's works are situated at Trail, on the Columbia River, distant from Rossland by railway between ten and eleven miles. Some 550 men are employed. Distinctive features here, in comparison with other reduction works in British Columbia, are the use of (1) the Huntington-Heberlein roasters and converters, and (2) the Betts electrolytic process for refining lead.

An idea of the extent of the company's operations may be obtained from the following figures, which are those for the calendar year 1910: Tons smelted, 445,210. Metal contents: Gold, 138,901 oz.; silver, 2,017,007 oz.; lead, 33,871,837 lbs.; copper, 5,282,139 lbs. The figures for the company's fiscal year ended June 30. 1910, were generally higher, especially in lead produced (42,368,816 lb,) while total value was nearly $400,000 greater.

Lead Smelting.—The lead ore supply is mainly heavy sulphide with comparatively little dry ore, the lead furnaces carrying a charge of from 35 to 45 per cent lead, as compared with the customary 10 to 15 per cent. More than 80 per cent of the ore received runs from 20 to 75 per cent lead, the remainder consisting of dry gold and silver ores, a small quantity of oxidized lead ore, and some pyritic mill concentrates. The lead beds are made up with heavy ores and concentrates only. They contain about 600 tons each, with 38 to 40 per cent lead. The sulphide, with lime rock, lead matte, etc., is treated in the Huntington-Heberlein roasters and converters. The resultant lead sinter is smelted in the blast furnace with dry ores, etc.

There are seven Huntington-Heberlein circular roasting furnaces 26 ft. in diameter, with hearths revolving once in three minutes. Stationary cast-iron rabbles work the ore through in about two hours. The making up of the roasting charge is important. An approximate analysis of the charge as now run is as follows: Lead, 40 to 44 per cent; iron, 10 to 13 per cent; silica, 8 to 11 per cent; lime, 7 to 10 per cent; zinc, kept under 10 per cent, if possible. Pyritic concentrates and matte form part of the charge. The converters number 24. They are 8 ft. 8½ in. in diameter, the diaphragm in four sections, bolted together. The time of converting varies widely with the charge, but averages three 10-ton charges in twenty-four hours, with a 10 to 12 oz. blast, which is decreased to 2 oz at the close. Properly made up, carefully fired, roasted, and converted, the product is fairly hard, yellowish or grayish yellow, showing some litharge, and is easily broken up with little fine material. In the furnace it runs with cool top and bright tuyeres.

Two lead blast furnaces are, respectively, 45 by 160 in. and 45 by 140 in. at the tuyeres. One of these has smelted as much as 260 tons in a day, but the average is about 190 tons of ore, beside by-products, matte, slag, etc., these constituting 20 to 30 per cent of the charge. The height of the charge is 17 ft. 6 in. above the tuyeres, and the blast used is 32 to 34 oz. The charge usually has about 85 per cent of Huntington-Heberlein roast, varying considerably with the ores, and some oxidized and silicious dry ore and lime rock. The coke is about 12½ per cent of the charge, not taking into account slag and easily melted by-products. An addition of 100 to 300 pounds of slag from the high-grade copper furnace is made to each charge to keep it open, make the furnace action uniform and reduce the percentage of zinc. The lead in the charge averages about 40 per cent, but it has been successfully run as high as 55 per cent. Sulphur is kept below 4 per cent, the lower the better, as the matte fall is less. The speed of running decreases markedly with a small increase of sulphur. From 30 to 40 per cent of the sulphur is eliminated in the blast furnace.

The slag is kept at about 31 to 33 per cent silica, 18 to 20 per cent lime, 24 to 30 per cent iron and manganese, 7 to 12 per cent zinc oxide, and 8 to 16 per cent alumina. It contains about 0.4 oz. silver and a little more than 1 per cent lead. With high zinc the lime is reduced to keep the slag fluid. It is not profitable to use silicious ores to bring the slag much above 33 per cent silica, as the furnace runs too slowly. Alumina gives no serious trouble. Iron and manganese may vary between the percentages above given without much difference in the furnace running. Scrap iron is added occasionally, although unnecessary when the charge is good.

The lead bullion flows from the side of the furnace into a kettle of fifty tons capacity, from which it is pumped into vertical anode molds. The matte and slag are tapped into a large receiver at the end of the furnace, the slag overflows into a granulating launder, while the matte is tapped from the receiver into pots. A single day's production of bullion has been as much as 130 tons, but about 75 tons is the present rate of production, with one furnace running. An average analysis of the bullion is: Copper, 0.22; manganese, nil; zinc, 0.098; antimony, 0.32; arsenic, 0.28; nickel, cobalt, and cadmium, nil; bismuth, 0.0133, and lead, 98.5 per cent; silver, 100 oz., and gold, 0.5 oz. per ton. A furnace is operated continuously for about seven months, then if accretions have accumulated sufficiently to make it profitable to blow it out and clean up the other furnace is blown in.

Lead Refining.—In the electrolytic refinery there are 240 tanks, each 3 by 8 by 3½ ft., arranged in cascades and pumps to keep the electrolyte circulating. Each tank has 20 anodes, which are spaced 4¼ in. apart in the tanks. Cathodes, consisting of sheets of pure lead, about 1-16 in. in thickness, are placed between and outside the anodes, 21 in each tank. The electrolyte used is lead fluosilicate with free fluosilicic acid, averaging 12 per cent acid and 5 to 6 per cent lead. The tanks are operated with a current density of 16 amp. per square foot of cathode area. The voltage averages 0.32 volt per tank, the contacts causing a loss of not more than 0.02 per tank. A tank is worked out in about eight days, and 15 per cent of the anodes, as scrap, goes back to the melting pot after having been washed. The cathodes are removed from the tanks, washed, melted, and cast into pigs of lead of 100 lb. each for the Chinese trade, and half that weight for other markets. An average analysis of 2,000 tons of lead ready for shipment was: Arsenic and bismuth, nil; zinc, 0.0005; silver, 0.0013; copper, 0.00075; lead, 99.9938; iron, 0.00075; tin, 0.0001; antimony, 0.0028.

The slime from the anodes is agitated in tanks with hot water, filtered and dried, and next melted in a water-jacketed reverberatory furnace lined with magnesite brick. The impurities are oxidized off, and doré metal running 960 to 975 parts gold and silver is obtained. The doré metal is parted with sulphuric acid. The silver sulphate is run into steam-heated tanks, where the silver is precipitated as a slime by bars of metallic copper. The silver and gold are collected, melted and cast into bars. The gold is 995 fine and the silver 999, the latter in bars of about 80 lb. each. Fine gold and some silver are sold to the branch of the Royal Mint, Ottawa, Ontario, and the United States Assay Office at Seattle, Wash. Silver finds its chief market in the Orient; refined lead is sold in eastern Canada, the Orient and other places.

By-products are copper sulphate and antimony. The copper sulphate solution, obtained in the course of treating the slimes, is crystallized into copper sulphate, making a commercial product used by farmers to kill smut in seed wheat.

Copper Smelting.—There are five copper blast furnaces, as follows: Two of 42 by 300 in. at the tuyeres; one of 42 by 263 in., and two of 42 by 240 in. The height of the charge is 9 ft. above the tuyeres, and the furnaces are operated with air pressure of 36 oz. Two forehearths are used with each furnace, but only from 0.25 to 0.50 per cent of the total matte is caught in the second settler. Most copper ores are smelted raw to a low grade first matte. The slag from the low-grade furnaces runs: Silica, 43 to 46 per cent; FeO, 14 to 15 per cent; lime, 20 to 22 per cent; copper, 0.1 per cent, and a very little gold and silver. The first matte, containing about 15 per cent copper, 27 per cent sulphur, and 56 per cent iron, is granulated, roasted in O'Hara furnaces to 10 to 12 per cent sulphur, blown in Huntington-Heberlein converters to a product which runs 3 to 4 per cent sulphur, and then smelted in a high-grade furnace, with suitable ores, to a matte running about 40 per cent copper, which last product is shipped to Tacoma, Wash., for bessermerizing. The slag from the high-grade furnace analyzes: Silica, 40 to 42 per cent; FeO, 26 to 28 per cent; lime, 16 to 18 per cent; alumina, 10 to 12 per cent, and copper, 0.35 per cent, with gold 0.02 oz. per ton. Some of this slag is used in the lead furnaces and part of its gold content recovered there.

General.—The ore supply comes chiefly from East Kootenay, Slocan, Nelson, Rossland and Boundary districts, and some from the neighboring State of Washington. Coke, of which about 225 tons is used daily, comes from Hosmer, Crow's Nest Pass, 249 miles distant. Limestone, chiefly for flux, is obtained from the company's quarry at Fife, 68 miles away. Requirements are about 200 tons a day, and cost is $1 per ton in the charge bins. Electric power is transmitted from Bonnington Falls, 33 miles distant, at 20,000 volts. At the smeltery it is stepped down to 550 volts. The total power consumption is about 3000 hp. The works are advantageously situated, with railway connections to all important mining camps on the Kootenay and Boundary districts, and with American roads to the southward. Mr. W. H. Aldridge is managing director of the Consolidated Mining and Smelting Company, of Canada (Ltd.), and has his headquarters at Trail.

New York Section American Electrochemical Society.

A meeting of the New York Section of the American Electrochemical Society was held at the Chemists' Club in New York City on Dec. 16, 1910. The chairman of the section, Mr. E. A. Sperry, presided. The meeting was very well attended.

The first part of the meeting was devoted to a general discussion of the fixation of atmospheric nitrogen, introduced by a brief paper by Dr. E. F. Roeber, who reviewed in succession the principles first of those processes in which air is treated, as it is, by means of electric spark or arc discharges (Bradley & Lovejoy, Birkeland & Eyde. Pauling, Badische Company) and then those processes in which the nitrogen is first separated from the oxygen in the air and afterwards caused to enter into combination with something else (manufacture of calcium cyanamide and synthesis of ammonia). As to the comparative power consumption in the manufacture of nitrates or nitric acid by arc discharges and in the manufacture of calcium cyanamide the following figures were given as representing best commercial practice: One kw-hour binds 17 grams of nitrogen in form of HNO_3 and 70 grams of nitrogen in form of calcium cyanamide. (In the latter case the power consumption in making calcium carbide is included.)

In the quite extended discussion which followed Messrs. Baekeland, Beckman, Loeb, Richards, Sperry, Tucker, Weedon, Whitney and others participated.

Mr. J. C. Clancy then presented a paper on his new process on the substitution of calcium cyanamide and electrolysis for cyanide in gold metallurgy. The paper is printed in full elsewhere in this issue.

Separation of Oxygen by Cold.*

By James Swinburne.

This industry has arisen, almost by accident, out of that of the liquefaction of gases. It had long been the ambition of scientific men to liquefy first one gas and then another; the liquefaction of such gases as oxygen, hydrogen and nitrogen being a sort of North Pole to be reached. It is doubtful whether reaching the North Pole is of any value to anybody but newspaper men, whereas the production of very low temperatures was bound to increase our knowledge very materially. Like most researches that appear at first to have purely increase of knowledge value, low-temperature work has proved to be, in addition, of direct commercial importance.

Though the separation of gases by cold has arisen out of the liquefaction of air, the two problems are not quite the same. Leaving out of account the details of the machine employed for the moment, we may consider the apparatus as a closed vessel, insulated to prevent heat getting in through the walls and having three pipes. At one pipe we may assume that air at the temperature of the room, but at a higher pressure, enters the machine; at a second and third, oxygen and nitrogen come out at the pressure and temperature of the room.

Air under high pressure has less internal energy than the same mass of air at the same temperature and lower pressure, so that if air is continually going into the apparatus at the temperature of the room and at high pressure, and its constituents are coming out at the same rate at the temperature and pressure of the room, more energy is coming out of the apparatus than is going in.

This is impossible as a permanent regime. It cannot be put right by less air coming out than goes in, because that would mean an accumulation of air. A balance can be obtained by taking out most of the air at the pressure and temperature of the room, with a high internal energy per kilogram, while a little of the air comes out at a low temperature, with less internal energy per kilogram. This portion may be quite small and may be liquid.

But the air is supplied under pressure and comes out at the pressure of the atmosphere, so it must be expanded inside the apparatus, and as there is no way of getting the energy of expansion out of the apparatus as described, it must be converted into heat, provided it is expanded irreversibly. This means loss of power, which is a small point, and production of heat just where it is not wanted, which is a serious matter.

If, therefore, in addition to the three pipes, there is communication by a shaft, and the apparatus may be arranged so that the expansion of the air works some sort of engine which turns the shaft so that work is given out, the yield of the liquid air must be larger. The ideal liquid-air machine would, therefore, take in compressed air and give out air at the same temperature, but at the pressure of the atmosphere; and a stream of liquid air, and as much power as possible, would be given mechanically through a shaft or other mechanical transmitter. It will be explained presently that the Linde separation process is nearly reversible, capable of being but little improved by giving out energy.

It is generally assumed that the problem of the separation of gases is substantially the same. This is not the case, however, and the overlooking of the difference has led inventors and designers of such apparatus into a series of absurd mistakes.

Take the ideal apparatus for separating gases; we have a pipe leading in gas under pressure at the temperature of the room, and two pipes coming out; one carrying oxygen more or less pure, and the other nitrogen more or less pure, at the temperature and pressure of the room. Now the internal energy of the gases coming out is greater than that of the compressed gas going in, and if the energy were alone to be

*A Faraday Society paper, presented at the December meeting in London.

considered, once the apparatus was started and got into running order as regards temperatures, air might go in at the pressure and temperature of the atmosphere, and come out as oxygen and nitrogen at the temperature and pressure of the atmosphere, the process being continuous and costing nothing appreciable. But as the apparatus cannot be made quite heat-tight in practice, the air might have to go in under slight compression, so as to have slightly less internal energy than the gases coming out, the difference being just enough to compensate for the leakage of heat through the casing of the apparatus. This is an ideal apparatus which several inventors have designed; but it is not possible to make such an arrangement work.

The energy is not the only quantity to be considered. Let us return to the simple case of an apparatus which is perfectly heat-insulated, fed with air at the pressure and temperature of the room, giving out oxygen and nitrogen separately at the same temperature and pressure. The entropy of the separated gaess is less than the entropy of the air going in, so if the process is continuous there must be a continual disappearance of entropy inside the apparatus, which is not thinkable. Air at a higher pressure, but at the temperature of the room, has less entropy, so it may be supposed we can get things right by compressing air until it has the same entropy as a compressed mixture, as the issuing gases have as they come out. We would then have an entropy balance.

This will not suffice in the ordinary course, however, because the compressed air must be expanded, and if that is done irreversibly inside the apparatus, more entropy is produced there, and to make a proper entropy balance either the expansion must be done reversibly or air must be so compressed that its entropy is reduced below the sum of that developed by any expansion and that of the separate gases. Imagine this done; have we a thinkable machine? No, because now our energy balance is wrong; we have air going in with less internal energy than the gases coming out.

It will be found on further consideration that the energy balance is got right by using imperfect heat insulation, heat leaking in to make up the extra energy of the issuing gases over that of the entering air; the entropy of the compressed air plus the entropy due to the heat leaking in, plus any entropy due to irreversible expansion or conduction of heat in the interchanger, being equal to the entropy of the gases coming out. If desirable the case may insulate perfectly, and some of the air or gases may be delivered continuously in the liquid state. The point to notice is that as the oxygen and nitrogen coming out have less entropy than if they were mixed at the same temperature and pressure, the apparatus has to be fed with compressed air, and energy is therefore needed to separate the gases. This point has been so often overlooked that it is necessary to dwell upon it. As far as I know, I was the first to publish it.

It has sometimes been supposed that because the gases are separated at a very low temperature the data determining the energy necessary to separate them do not depend on the difference of entropy of the separate gases and the mixture at the temperature of the room, but at the temperature of separation. This is erroneous and may give rise to further mistakes. That it is erroneous is clear from the illustration. Suppose the difference of entropy of cold gases separate and cold gases mixed is less than the corresponding difference at the temperature of the air; even if the entropy of the entering air is reduced enough to compensate for this only, and not for the entropy of the issuing gases, the entropy balance of the machine as a whole is wrong.

Heat leaking in is difficult to value, as there is an irreversible change as the heat is conducted to the cold gases, which means increase of entropy; and there is increase on entropy, due to irreversible expansion. For simplicity take a heat-tight case, and the energy balance kept right by drawing out a small stream of liquid air. Then, if there is no irreversible process inside the apparatus, there is no growth of entropy in it; and the entropy of the gases coming out, plus the entropy of the liquid coming out, must be equal to the entropy of the air going in. In other words, the entropy balance depends on the entropy of the issuing and entering streams, and not on the entropy of the gases at some inside point where they are at very low temperatures, though the separation actually takes place there.

To make the matter clearer it may be better to put the entropy question more fully. The change of entropy of a gas may be split up into entropy of change of volume, which varies as the logarithm of the volume or of the free path of the particles, and entropy of change of temperature, which varies as the logarithm of the speed of the particles. We may call these two the volume and the speed entropies ϕ_v and ϕ_s. When two gases mix, the volume of each increases in a way—that is to say, it pervades a larger space, and the molecular free path of each particle is increased if you take into account the collisions with other particles of the same gas only. The mixture of two mutually inert gases thus involves increase of entropy, which I will call entropy of mixture ϕ_m. As this depends solely on the logarithms of the free paths, it depends, in the case of two gases at the same temperature and pressure, only on the relative volumes of the gases before they are mixed.

There is still another point to be considered. If a perfect gas is, say, expanded at constant temperature, its internal energy remains the same; but such gases as oxygen and nitrogen have a slightly larger internal energy at the larger volume, as discovered by Thomson and Joule, and this involves an increase of entropy in excess of that due to the increase of mean path; this may be called the Kelvin entropy or the Joule entropy; preferably the Kelvin entropy, as the term joule, being used to denote the unit of heat, might give rise to confusion. We may call this ϕ_x, if a symbol is ever wanted.

We may imagine a closed apparatus with entry pipe for air and exits for nitrogen and oxygen. We have then air going in at one pipe and oxygen and nitrogen coming out at two others, and heat leaking in from the outside. The conditions for permanent regime are that the internal energy of the O and N coming out must be equal to the sum of the internal energy of the air entering and the heat leaking in. If this were all, of course, we would arrange no heat leakage, and let the air come in and the oxygen and nitrogen come out at the pressure and temperature of the air. But we must get the entropy balance right, too—that is to say, that the entropy of the oxygen and nitrogen coming out must be at least equal to the entropy of the air going in, and if heat is leaking in, or if there is any other irreversible process such as free expansion going on inside, or irreversible conduction in the interchanger, the entropy of the gases coming out must be greater.

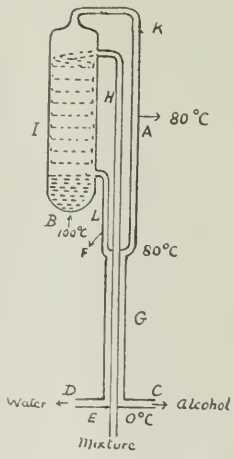

FIG. 1.—IDEAL DIAGRAM OF ALCOHOL STILL.

So many people are unfamiliar with this way of discussing such questions, that it may be better to deal with the matter also along other lines.

As the separation of the oxygen and nitrogen is carried out in a rectifier, we may discuss the action of the rectifier, taking an alcohol rectifier first as being more familiar, and not involving out-of-the-way temperatures; though, as a matter of fact, it

is in a way very much more troublesome to discuss fully.

Fig. 1 shows an ideal, or paper, diagram of an alcohol still reduced to a simple form. A mixture of 50 per cent alcohol and water at 0° C. comes in at *E* and flows through a heat interchanger *G* until it reaches 80°, the boiling-point of alcohol. It then passes up the pipe *H* to the top of the rectifier *I*. The pipe zigzags, or winds, down to a point where the temperature is 82°, the boiling-point of the mixture. The liquid is then discharged into the rectifier, which may be full of trays, and trickles down to the bottom and out by the pipe *F*, and thus to the interchanger *G*. The alcohol vapor comes off by the pipe *K*, and is nearly all condensed at *L* and passed to the interchanger. The water and alcohol come out at 0° C. at *D* and *C*.

The rectifier must have heat supplied at *B* to boil off enough steam to rise against the trickling fluid, and, assuming all the parts of the apparatus heat tight except where arrows are put, we have coming out of the system heat at *A*, where the alcohol vapor is condensed, and at *F*, where the water coming out at 100° is cooled to 80° before entering the interchanger. As alcohol and water heat on mixing, the output from *D* and *C* have higher internal energy than the ingo at *E*, but except for that, all the heat that goes into the interchanger in the pure water and pure alcohol goes into the mixture and goes back into *I* by the pipe *H*.

Suppose the still deals with 1 kg of mixture per minute, 500 grams of water come down the pipe *L*, so the heat given out in cooling the water to 80° is obtainable. The heat of mixture of water and alcohol gives the extra internal energy of the output. If the heat capacity of the mixture were the same as that of the alcohol and water separately, the water and liquid alcohol entering the interchanger would just heat the mixture to 80° as they cooled to 0°, but, as might be expected from their mixture evolving heat, the heat capacity, in which is really involved the disgregation energy, is higher, so either the water must be admitted above 80°, or the alcohol must not be all condensed before entering.

As we know the heat of vaporization of alcohol, we get the heat we could get out at *A*. Knowing the quantity of heating coming out, we know the heat put in at *B*. It might be thought that this would be anything the workman liked; this is not so, for if we put in too much, water would come out with the alcohol, and if too little, alcohol would come out with the water.

The broad result is that heat has to go in at 100° and come out almost wholly at 80°, the heat being roughly the heat of vaporization of the most volatile liquid.

To see what happens when we do the separation by mechanical power, we can imagine an ideal heat engine worked so as to deliver heat at 100° and to take in heat at 80°, or other temperature. If it does not get in enough at 80° it must make up the difference by direct degradation of work into heat or better by taking in heat at 0°: if it gets in more than is wanted at 80° it can deliver at 0°. If the process merely involved taking in the heat of evaporation of 500 grams of alcohol at 100°, and giving it out at 80°, calling the heat *H*, the engine would have to take in $H\,353/373$ at 80°, or $353^\circ A$, and by doing $20\,H/373$ of mechanical work on the medium, *H* would be put into the rectifier at 100° C. The $20\,H/373$ left over could be let down to 0, doing $(353-273)/353 \times 20\,H/373 = 0.0122\,H$.

Thus, if the heat of vaporization were 100, the first engine would do 5.36, and the other engine would recover 1.22, so that the total mechanical work to be done would be 4.15 of the heat of vaporization of the alcohol, or 18,000 joules per minute, or 300 watts. Instead of adopting the rough statement that we have to supply the heat of vaporization of the alcohol, we may work the example out approximately.

The alcohol vapor at *K* carries over 436,000 joules, as compared with its liquid state at the same temperature. This is not all given out at *A*, because a little is wanted for the interchanger *G*. This has mixture coming in, being heated from 0° C. to 80° C., and 500 grams of water and 500 of liquid alcohol, both at 80° C., will not heat it, as the specific heat of the mixture is higher than the mean of components. This is to be expected, because equal parts of alcohol and water give out 29,000 joules per kilogram on being mixed, so that the disgregation energy of the mixture must be greater, and the heat taken in between 0° and 80° is largely disgregation energy. The extra heat needed is about 34,800 joules. This is returned to the rectifier by the hot mixture, so we get out $436{,}000 - 34{,}800 = 401{,}200$ joules at *A*. We also get 42,000 by the water coming out at *L* at 100° C. and being cooled to 80° C. before entering the exchanger *G*. We thus have to supply 443,200 joules at 100° C. at *B*.

The heat of the water in *L* may be utilized. The difference of entropy of 500 grams between 100° C. and 80° C. is 116.5 in practical units, so the heat put in at 100° C. is $373 \times 116.5 = 43{,}500$ joules; of which 42,000 are from the heat of the water and 1500 from work done. This leaves 399,700 to be supplied by an ideal engine working between *A* at 80° C. and *B* at 100° C. Such an engine will take in 378,280 as heat and put in 21,420 as work. But there are 401,200 joules coming out at *A*, so there is a balance of 22,920. An engine working between *A* at 80° C. and 0° C. will utilize 7820 joules out of this, rejecting 15,100 at 0° C. We thus have $1500 \times 21{,}420 - 7820 = 15{,}100$ joules to put in mechanically, or 252 watts.

One of the chief difficulties in this sort of calculation is the uncertainty as to the numerical data. This case is also complicated by the internal energy of the alcohol and water separate being greater than that of the mixture.

To get rid of the effect of the internal energy of the separated liquids in the last case the arrangement shown in Fig. 2 may be discussed. Here mixed alcohol and water as vapor comes in at *O*. It goes to an interchanger *G*, where it is cooled down to 80° C., being thus condensed, and it flows by the pipe *H* to the rectifier, which is as before, except that it gives out steam at *L* instead of water. The alcohol coming out at *K* is taken away as vapor. The mixed vapors condensing in *G* will give off much more heat than is necessary to raise the alcohol vapor from 80° C. to 100° C., so heat will be given off along *G*.

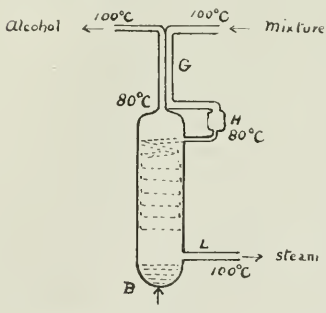

FIG. 2.—IDEAL DIAGRAM OF ALCOHOL STILL.

For want of data as to heat of vaporization of mixtures of alcohol and water I have taken the heat that would be given out by 500 grams of each and deducted the extra internal energy, 29,000. This gives 1,541,550 joules given out along *G*, after deducting 950 for heating the issuing alcohol vapor. We must therefore supply this at 100° C. at *B*. As this large amount of heat is given off all along *G* it is difficult to know its value. To get it we would need a table giving the boiling-points of the range of mixtures of alcohol and water, and the composition of the vapor coming off, and to be quite accurate we should have a column of heats of vaporization.

For simplicity we shall not be far wrong if we take the heat as being given out at 94° C. This needs 25,200 joules given mechanically and 1,541,550 taken in as heat from *G*. Another engine will have to put in 1120 joules as work, taking in heat at 0°, and giving out 3805 at 100° C. We have thus 26,320 joules per minute, or 438 watts. This figure is most likely rather inaccurate, as the data are doubtful. The example is complicated by the heat of combination of alcohol and water

too. Broadly speaking, what has to be done is to put in heat at the boiling point of the less volatile liquid, taking out heat at a temperature between it and the boiling point of the more volatile liquid. This involves either supplying the system with heat at one temperature and recovering some of it at a lower temperature, or supplying energy mechanically.

The case of separating oxygen and nitrogen is simpler, as there is no development of heat on mixing the gases. It is exceedingly unlikely that there is any liberation of heat on mixing the liquids, but in the ideal case discussed next, if there were such heat it would not affect the reasoning, as its influence would cancel out.

Suppose for simplicity we are operating, say in Dis, at a temperature of 90° A, and we have a system as shown with a pipe leading in air at 90° A, and two pipes delivering oxygen and nitrogen at 90° A.

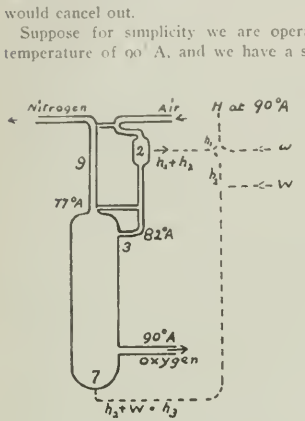

FIG. 3.—DIAGRAM OF SEPARATION OF OXYGEN AND NITROGEN.

Air comes in at *A* and the pipe branches, most of the air going to the cooler 2, where it is reduced to say 82° A, a good deal being liquefied. The partly condensed air then goes into the rectifier at 3. Nitrogen comes out as gas at 4, at 77° A, and is raised to 90° A by a portion of the entering air going down the interchanger 9. Heat has to be supplied to the rectifier at 7 to boil off the oxygen, and heat is given out at 2. Thermodynamic engines take in heat from 2, and deliver some of it at 7 and the rest to the outside. We have to find the power necessary to drive the engine to separate a kilogram of air per minute, or the energy to separate a kilogram of air. A kilogram of separated air in an ideal engine with semipermeable pistons could do 13,180 joules in allowing the gases to mix at 90° A; 13,180 joules must therefore be done in separating them. As the internal energy of the separated gases is the same as that of the mixture, this work must be wholly degraded into heat. The system that takes in air and gives out oxygen and nitrogen at the same temperature and pressure must therefore give out heat, taking in work; and the heat for each kilogram of air is thus 13,180 joules.

We do not really need to trouble ourselves as to what goes on inside our closed system. We do not need to know anything about the heat of vaporization, boiling-points, or heat of mixture; all we have to know is the work that can be imagined as obtainable by a suitable arrangement for mixing the gases, and we then know the mechanical energy ideally necessary to separate them, assuming the system to have no irreversible process going on inside.

But it is worth while to look inside.

Call the heat given out at 90° A, H, and 90° A, h_1 and the temperature of 2, Θ_2. Let the heat H be given out by a thermodynamic engine taking in work w_1 and heat h_1 from 2 at Θ_2. Then H is made up of $h_1 \times w_1$ and $h_1 = H\Theta_2/\Theta_1$, and $w = H(\Theta_1 - \Theta_2)/\Theta_1$. The rest of the heat given out at 2 is taken in by a second thermodynamic engine at Θ_3 and given to the rectifier at Θ_3. Call this heat h_2; then the heat given to the rectifier is $h_2\Theta_3/\Theta_2$, and the work done by the second engine, W', is $h_2(\Theta_1 - \Theta_2)/\Theta_2$. But $H = W' + w$ and $h_1 + h_2 = h_3$, as the rectifier takes in and gives out the same amount of heat. From these equations we get $w = H(\Theta_1 - \Theta_2)/\Theta_1$, and $W' = H\Theta_2/\Theta_1$.

Suppose that instead of working at 90° we lead the inlet and two outlet pipes through an interchanger, and work at 273° A, or say 270° A, to make a round number. The work W is not altered, as the conditions of that engine are not interfered with; but the first engine that takes in heat h_1 at Θ_1 now has to give it out at 270° A instead of 90° A. It is simpler arithmetically to imagine a third engine taking in the heat H at 90° A and giving it out at 270° A. This engine does 2 H.

It is hardly necessary to repeat that the mathematical power needs vary as the absolute temperature, as the work ideally obtainable on mixing the oxygen and nitrogen at atmospheric pressure varies as the absolute temperature.

Take now the case of dry air to be separated completely into oxygen and nitrogen. The work ideally obtainable from a kilogram of the gases mixing is 40,000 joules, so to separate a kilogram a minute needs 666 watts in a perfect machine where all the processes are reversible. This would come out fairly expensive on a very large scale.

In this case it has been assumed that the air is to be separated completely into pure oxygen and pure nitrogen. It does not follow that it pays to separate in this way unless both gases are wanted pure in the proportion of four to one. If oxygen alone is wanted, it does not pay to make pure nitrogen for that means abstracting oxygen from a mixture with very little oxygen, while air is obtainable at no cost. To separate a kilogram of air at 0° C. into pure oxygen and nitrogen needs 40,000 joules to be converted into heat*; to take out half the oxygen needs only 17,000 joules, but as this gives only 115 grams of oxygen, 34,000 joules are needed to give the same weight of oxygen. If the oxygen is wanted for enriching air for combustion purposes, it is cheaper to extract it impure. But for pure oxygen the most economical proportion to extract—on paper—is about 50 per cent. In practice it may be better to take out a little more, as the less gas you pass through the apparatus the smaller it may be.

It might be said that given a kilogram of air cooled down, a machine that extracts all the oxygen does its work better and is cheaper; this is not the case, however, as air does not cost anything appreciable, even cooled.

We have therefore the problem of taking in heat at a temperature of about 82° A and giving it out at 90° A, and the temperature of the room, say, 290 A.

There are broadly two methods in use. It is not necessary to trace the history of the liquefaction of gases, and to follow out the ingenious intensification methods. They are all well described in the literature of the subject.†

The first method is Linde's. This takes advantage of the discovery by Kelvin and Joule that such gases as air have less internal energy when compressed. If you feed a heat insulated system with air under compression and let it expand before it comes out, the air coming out must at first take out more energy than the air going in carries with it; so the inside of the apparatus must get colder and colder. If the outcoming air comes through an interchanger, it will come out at the same temperature as the ingoing air, so the other end of the apparatus must get colder and colder until some of the air is liquefied. The balance will come when the internal energy of the gas and liquid air taken out is equal to that of the compressed air going in.

In practice the same machine does the liquefaction and separation; but it is simpler for our purpose to treat a machine in which air is compressed and allowed to expand as a thermodynamic engine, using the liquid air as a means of extracting heat at a low temperature. It was this invention of Linde's that made the production of liquid air, and his subsequent invention of combining the rectifier with it that made the commercial production of oxygen thermodynamically from air possible.

---

*For simplicity, atmospheric pressure is taken as a megadyne per square centimeter; and heat is taken in joules, not calories; entropy, when necessary, can be taken in entrops, which, multiplied by the lowest available temperature, give the incurred waste in joules.

†The engineer will find G. Claude, "Air Liquid," and Ewing, "The Mechanical Production of Cold," interesting.

The other invention is due to Claude. It was, of course, obvious that cold could be produced by compressing the air at a high temperature and then expanding it so as to do external work at a low temperature, and the merit does not here lie in the idea. But to work out such a system is a very different matter. The practical difficulties in making an engine that would give out any reasonable power at a temperature of 80° A are very serious indeed.

So far I have discussed the subject on what are sometimes incorrectly called theoretical lines, that is to say, ideal lines, in which all sorts of assumptions are made so that the discussion should be easier. Thus I have discussed perfect heat insulation and completely reversible changes and perfect thermodynamic engines. The principles are the same on a large scale; but there is a leakage of heat, and all sorts of irreversible changes of heat, and a compression pump does not come up to the thermodynamic ideal in efficiency. In the industry as now carried on the question of efficiency is of very little importance. Oxygen is sold in small quantities in bottles; and the costs of compressing, handling, selling, delivering and so on, and the collection of the empties, are enormously large in proportion to the mere cost of making. Thus we have discussed oxygen, taking 34,000 joules for 230 grains, or about 2 kw-hours per cubic foot.

The great future for the separation of the gases is in the direction of making nitrogen for the manufacture of calcium cyanamide, and oxygen for use in blast furnaces, and other work where a high temperature may be worth the extra cost. It is, therefore, important to see how far the gases can be produced on a large scale at prices within a reasonable margin.

We may, therefore, sum up the rectifying part of the plant as an apparatus which gives up heat at a low temperature, say 82° A, and absorbs heat at, say, 90° A, the heat taken in at 90° A being equal to that given out at 82° A. A refrigerator must, therefore, be a thermodynamic engine capable of giving heat at 90° A, absorbing heat at 82° A and giving out heat at the temperature of the works, say, 290° A.

It is generally supposed that Linde depended on an irreversible expansion of a gas. This is not the case, and I would put the matter in another way.

If gas is compressed, cooled to, say, 290° A, and sent into an interchanger, out of which it comes by a return pipe at the pressure of the air, there must be cooling going on inside, as the air delivered has higher internal energy than the air going in. You have therefore an apparatus for producing cold—that is to say, for absorbing heat at a temperature below the room. The question is, what is the lowest temperature at which this apparatus will take in heat? The lowest temperature is that of the boiling-point of the liquefied gas at the pressure of the atmosphere. If the apparatus is working in such a way that it can take in heat H at temperature O_2 the increase of entropy is H/θ_2. But if instead of working in this way the heat is taken in at Θ_1, which is a higher temperature, the increase of entropy is H/θ_1, which is less, so the apparatus makes up the deficit of entropy by irreversible expansion.

On starting up a Linde machine it begins by abstracting heat from its own air and metalwork at the temperature of the air, so the entropy is made up by irreversible expansion. As the temperature at which the heat is absorbed falls, the irreversible expansion gets less and less, until finally the whole of the gas is turned into liquid. Then there is some production of heat by the liquid passing from a high to a low pressure through an obstruction, and also some slight evolution of gas to cool the released liquid from the boiling-point under the high to the boiling-point under the low pressure. The irreversible loss due to liquid is $pv/10$ in joules, where v is the volume of the liquid. If the compression is small, this is small, but if it is high, pv may be considerable. It would be quite easy to get this energy out by means of a little engine, as there is no expansion and no difficulty in lubrication, and it would be worth while on a large scale The liquid may also be cooled to a lower boiling-point while still under pressure, so that there is no irreversible evolution of gas on its being exhausted from the engine.

The refrigerator has to do the work of two thermodynamic engines, for it has to abstract a lot of heat at one temperature, give a large proportion back at a higher temperature, and give out heat at the temperature of the works. The ideal apparatus consists of a compressor with water-cooling delivering gas at the temperature of the works and a high pressure to an interchanger. The pressure is chosen so that the gas liquefies under it at 90° A, giving up its heat to the rectifier. The liquid at 90° A is then cooled in an interchanger to 82°, and it is then passed through a hydraulic engine, coming out at atmospheric pressure and temperature 82°. It is now vaporized, taking in heat at 82°, and goes out by the delivery side of the interchanger.

The process described is not quite reversible, because the specific heat under constant pressure of the gas coming down the interchanger is greater than that of the gas coming up under atmospheric pressure; there has therefore to be an abstraction of heat all along the interchanger to make up for this difference.

The idea of this apparatus is something like that of an ordinary carbonic acid machine worked under different conditions. If a carbonic acid machine were worked in the tropics and the cooling water were above the critical point of CO_2, the compressor would supply compressed gas only. Some sort of refrigerator would be necessary to liquefy the CO_2, and the liquid CO_2, would then be evaporated at a low temperature. We thus have three temperatures to consider—the temperature of the works at which heat due to compression is given out, the temperature at which the CO_2 is liquefied under pressure and the temperature at which the CO_2 is finally evaporated. In a refrigerating plant three temperatures would be a nuisance, so a fluid is chosen with a critical point above the temperature of the works. But for rectifying three temperatures are necessary—the temperature of the works, the temperature of the boiling-point of the least volatile liquid and the temperature of the liquefaction of the mixture. We can therefore use a fluid which is compressed at a temperature which may be much above the critical point of the liquid.

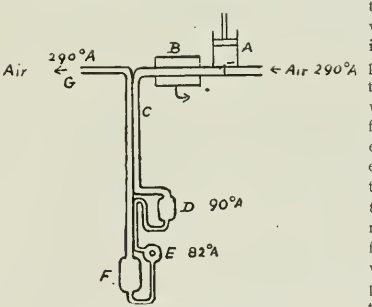

FIG. 4.—IDEAL LINDE REFRIGERATOR.

Fig. 4 shows an ideal Linde refrigerator. The compressor A delivers a fluid, say air under pressure, to the cooler B. Heat comes out there at the temperature of the works. The air goes on down through the interchanger C until it is cooled to 90° A. Then it is cooled in D, which is really a coil of pipe immersed in the oxygen to be evaporated at the bottom of the rectifier. From D the liquid, still under pressure, goes down the interchanger until it is cooled to 82° A, and it then works a little engine, E, and comes out into F. F is really a coil of pipe in the liquefier of the rectifier. The air is evaporated in F, and passes up the interchanger and escapes at G.

There are some points to be noticed. As already pointed out, the interchanger must take in heat by leakage, which is an irreversible process; and the heat taken in at F will be greater than that given out at D, as it takes more heat to vaporize a liquid at a low pressure and temperature.

The processes in this refrigerator are, however, substantially reversible.

If schemes for dealing with liquefied gases are examined, it will often be found that a liquid is being condensed or evaporated by a gas in the interchanger. That is always a piece of bad design involving irreversible change. It may be inevitable, of course, but it should be recognized as an evil which must be carefully watched.*

Linde points out that the mechanical work necessary may be reduced by working between two high pressures. But there is a limit to this, as if both pressures are very high the lower temperature limit of the plant is reduced; so the limit is reached by the lower pressure, which must be low enough for the fluid to evaporate at 82° A, or whatever temperature the heat has to be extracted from the rectifier. If we choose a fluid, say nitrogen, this gives the lowest pressure that can be used. Then the other pressure must be high enough for the liquid to condense at 90° A. Some latitude can be got by control of the pressures in the rectifying plant, but it is simpler for the present to take the rectifier as working at atmospheric pressure for the sake of ease of calculation.

The refrigerator, then, has to supply for each kilogram of air split into pure gases 135,000 joules at 90° A, absorbing 135,000 at 82° A. The liquefying of this fluid is in contact with a fluid that is being evaporated, so that that part of the process is ideally reversible. The re evaporation is in contact with the air which is being liquefied, so that part of the process is ideally reversible. The passage of the liquid from the high to the low pressure can very easily be made to give out work. It is not the same problem as dealing with expanding air, as the volume is small, the pressure constant and the liquid acts as lubricant. The process, so far, is essentially reversible. The specific heat of compressed gas is higher than that of the same gas at a lower pressure, so a little allowance must be made for that. It is thus possible to use a process which has no external work done by expansion of cooled gas in such a way as to get little loss by irreversible changes.

To work out an example, nitrogen can be taken as the fluid, as it is easier to discuss than a mixture. To get 135,000 joules, taking heat of vaporization of nitrogen 200 joules per gram, we need 675 grams of nitrogen, and we can liquefy this at 90° A under about four atmospheres, evaporating it again at 82° A at two atmospheres. Taking the density of liquid nitrogen as 0.8, the hydraulic engine gives out 170 joules, a mere trifle in this case, and the compression of the nitrogen from two to four atmospheres needs 37,000 joules, so we need under 37,000 joules. As the separation needs 40,000, this is clearly an erroneous figure, but the data are very uncertain. We must need more than 40,000.

To work on a large scale with atmospheric pressure in the separator and four and two in the refrigerator would be quite out of the question. The volumes of air would be enormous, and the interchangers would be very inefficient. Those who have had to work with gases that have to be heated or cooled will realize the extent of this trouble at once. To make the plant practical it will be necessary to work the rectifier under pressure. This raises the temperature of the rectifier; but that does not mean that we can separate the gases more economically; the cost of separation depends, as already stated, on the difference of entropy of the gases entering and leaving the plant, not on what goes on in the plant, provided there are no irreversible changes. Using pressure allows the refrigerator to be worked at higher pressures, so that the interchanger may become practical.

Assuming the ideal energy needed to separate a kilogram of air into its gases to be 40,000, the question is: What will it cost in practice? On a large scale it may be safe to say 100,000 joules. We would then get 230 grams for 100,000 joules; or a ton would need 120,000 kw-hours. Taking the cost of a kilowatt hour as low as 0.2 cent, this means $250 a ton.

It does not look as if oxygen at this order of figure could be used for blast furnace work. Taking a blast as using four and a half tons of air per ton of iron, to increase the oxygen content of 1 per cent of the oxygen content the cost comes out at $2.50 per ton of pig. This does not look as if it could be of use.

The principle of separating gases by cold can be applied to other gases. Thus hydrogen may be purified, so that water-gas can be used as source of balloon gas. Methane can be separated out by solution in water under pressure.

Chlorine can be separated from the impure gas from the anode chambers in electrolytic works. Such chambers are generally worked under a slight exhaust to avoid troubles due to leaks. Air thus leaks in, and the chlorine coming off is moist and impure. Chlorine can be condensed into water, and it might appear that condensing such gases as chlorine and methane into water would allow of their being separated with less expenditure of energy than the entropy consideration demands. This is not so. It takes greater pressure to get the gas into the liquid out of a mixture than the solution exerts in an atmosphere of the pure gas.

Chlorine, by the way, is easier to handle than is generally supposed. It can be pumped in iron pumps flooded with sulphuric acid. It can also be dried and then compressed in iron pumps lubricated with sperm oil saturated with chlorine. It is not necessary to dehydrate it absolutely for compression up to, say 50 lb.

There may be other gases that can be separated or purified by liquefaction and rectification; it is difficult to think of any case where the principle cannot be applied.

Progress in Ore Dressing in United States and Mexico During 1910.

By H. A. Guess.

Water Concentration.

The record of progress during 1910 compares favorably with that of any recent year. If it were possible to make a general observation outlining the direction the various betterments have taken it could be said that progress and improvement had been made chiefly in the way of detailed steps looking toward the recovery of the mineral, without unnecessary sliming—either by stage grinding with mills, with recovery of the released mineral before the second grinding, or by carrying roll recrushing to such a degree of fineness that in certain cases it largely replaced the work of grinding mills. Coupled with this has been the attention devoted to the better classification of table and vanner sizes and especially to the more complete removal of all slime from feed going to stratifying tables. Equally important, too, have been the little changes and betterments—bulking large in the aggregate—which have been going on at the different plants over the country, all tending to economy in operation, the handling of a larger tonnage, the making of a cleaner product or a higher recovery.

Following the ore in water concentrating processes by steps it may be said that nothing noteworthy in the way of new machinery or arrangement has developed during the year in coarse or dry crushing preparatory to concentration.

In jigging—where jigging is used—the Hancock jig, with its large capacity, has continued to find favor, particularly in the lead district of Southeast Missouri, and all mills built there within the past two years use that type of jig, some 9000 tons per day being at present handled there by that system.

In screening other than for sizes finer than 1 mm, trommels continue to be the more usual equipment, but of late the impact screen, which after its earlier trials of some ten years ago has fallen rather into disrepute, has been improved mechanically so that its use is greatly increased, some of the largest of the

* There is another factor very common with regard to gas issuing from a nozzle. Suppose it runs out into the atmosphere, it is thought that as it has to expand against the pressure of the atmosphere, doing work in joules equal to a tenth of its increase of volume, it must be cooled to a corresponding degree. This is a mistake nearly everyone makes until he thinks of it under a second time. As such an error would give rise to many misapplications in connection with the liquefaction of gas, it is not impertinent to call attention to it.

concentrators on porphyry copper ores now adopting impact screens entirely.

For fine crushing the tendency has been to carry the work as far as possible with rolls, and where grinding mills are used it has been in many cases found profitable to conduct the operation in two stages with classification and table treatment in between, the coarser sizes being returned from the roughing tables to the second mill. Certain of the porphyry concentrating plants have adopted and within the past year extended this system with improvement in recovery, as well as increase in tonnage per mill section and per horse-power consumed. During the year extended working tests were carried out under the above-mentioned system in comparison with direct crushing with Nissen stamps and the advantages of the stage-grinding system, in such comparison, were clearly apparent in tonnage output per square foot of mill floor space, in power consumed and in percentage recovery. Mills of the Chilean type appear to find most favor, especially among the larger plants, although altogether there are doubtless more Huntington than Chilean type mills in use throughout the country. Occasionally tube mills are seen in concentration plants for fine grinding of certain middling products, and their use within the past year has been on the increase, particularly the more recent Hardinge conical type. The tube mill has heretofore been regarded chiefly as a slimer, due to its extended use for that purpose in cyaniding, but by suitable adjustments in rate of feed and ratio of water it is showing encouraging results as a fine granulator in comparison with the more usual grinding mills, the percentage of slime formed being not excessive nor the horse-power and supplies unduly high.

The classification of table and vanner sizes has received much attention during the past year, especially in regard to the more complete removal of all slime from feed going to stratifying tables. The removal of slime is not difficult in the coarser sizes of table feed, but in the finest sizes it has been impossible by any continuous discharge type of hydraulic classifier to make the separation from slime clean cut. The usual procedure in such cases has, therefore, been to recover as much of this slime as possible by collecting the table back-water for subsequent vanner treatment and to let the rest go to waste with the table tailing. In cyanide practice mechanical classifiers are largely used for the separation of fine sand from slime and the same idea is now beginning to be applied at some of the larger water concentrating plants. At the largest plant in Southeast Missouri mechanical classifiers similar to the Esperanza drag classifier of cyanide practice, only a little longer and arranged with spray pipes for washing, have been installed—one in each 600-ton mill section—taking the undersize of 1-mm trommels and separating therefrom all slime as overflow product and all sand as a washed drag product, the slime after thickening going to vanners and the sand going to hydraulic classifiers for division into various sizes of table feed. Another system lately adopted on a large scale by certain of the porphyry copper concentrators, and looking to the same elimination of slime from all table sizes, is the use of intermittent discharge hindered settling classifiers of the Janney type, which deliver the classified products in thickened form. The Richards vortex and hindered settling classifier and also the more recent pulsating classifier continue to have a wide use.

In table concentration each year sees new models—all practically of the original Wilfley type—put upon the market. Joplin was about the last of the older established districts to awaken to the losses being made through inattention to the treatment of sizes too fine to jig and in this and its adjoining districts many tables have of late been installed as adjuncts to the older jigging plants. A large proportion of these are of local manufacture, some half-dozen different styles being on the local market there, all of them of very good construction. In the other and better known districts of the United States and Mexico the Wilfley, Overstrom, Card, Deister and James continue to be the types more frequently seen and in about the order mentioned

The Deister No. 3 table competes fairly successfully with the vanner on slime, its merits being more or less confirmed in that one of the large porphyry copper concentrators now nearing completion is adopting the Deister No. 3 for its slime concentration. In general, however, for slime concentration vanners continue to be the standard machine, although there is recently some revival in the use of buddles on slime, the larger installations being of steel frame with concrete top; also some interest has been aroused in traveling canvas-belt machines, such as the Craven slimer, which in the matter of recovery does good work. It is usually considered that in vanners the Frue type does a little better where there is considerable mineral, the Johnson suspended type being more in favor for second treatment or where the mineral is in small amount. The Isbell vanner supported from a steel girder foundation, instead of the more usual four-post construction, has been introduced this year and may in practice present some features of improvement. Retreatment of vanner tailings over a second series of vanners is now becoming accepted practice unless the ore is very lean, the first tailings being usually thickened before going to retreatment.

The disposal of tailings is, with the advent of larger mills, becoming something of a problem, especially in a flat country where surplus water is not available. In Missouri, where such conditions exist, the more recent plants use dewatering devices feeding the comparatively dry tailings to an inclined conveyor belt which acts as a stacker, the motor drive being at the upper end. Extensions to the belt are made as occasion demands, the upward slope being maintained—usually about 16 ft. to the 100 ft. It may be noted that for such work the less troughing the belt receives the less tendency to crack and the longer its life, and this in less degree is also proving the experience in the handling of dry material with conveyor belts.

Cyaniding.

In cyaniding the practice of all-sliming treatment is on the increase and the tube mill remains the approved machine for such work, although at some of the larger plants comparative tests are still being run of tube mill versus pan, for fine grinding and sliming, and at the Homestake a number of Wheeler pans are in regular service. In connection with the tube mill as a slimer a comprehensive series of grinding tests at Pachuca—details of which were given in a paper by Mr. V. B. Therrod before El Instituto Mexicano de Minas y Metalurgia—led to the conclusion that the grinding efficiency increases with the percentage of solids in the feed up to 55 per cent to 60 per cent; that it also increases with the quantity of ore fed per minute to a point which varies with the dimensions of the mill, and that the horse-power efficiency appeared to be lower in the mills of larger diameter—5 ft. x 20 ft.—than in the smaller mills—4 ft. x 18 ft.

In the separation of sand from slime for purposes of return for regrinding or for leaching, the Dorr classifier continues to have a wide use, and more recently, to some extent, drag classifiers of the Esperanza type. For the same purpose the Caldecott diaphragm cone is also being adopted, and its use seems on the increase.

For the agitation of slime preparatory to filtration the Pachuca tank or its equivalent continues to be the accepted system for new installations, and at several plants these tanks are of late being connected up in series, the first overflowing to the second, and so on, thus giving continuous agitation in transit without loss in head; with simplicity in operation and equal percentage extraction. Considerable interest has been aroused by the Just process, which uses agitation by air through porous silica brick placed as a floor in flat-bottomed tanks, the air being introduced beneath and coming up evenly through the brick. The same material is also being used to some extent as a filter in leaching tanks.

Much attention during the year has been devoted to the development and perfecting of filtering processes for slime. Various patented filters, both vacuum and pressure, have been

added to the already large number of such devices on the market, so that, with intelligent selection of the machine best adapted for each particular type of slime, steady progress seems assured in the matter of filtration. In this connection, too, the use of slime thickeners of the Dorr type is relieving the work of filtration to some extent. Of the various filtering devices now on the market the best known are, perhaps, the Butters, Merrill, Burt, Grothe-Carter, Ridgeway, Kelly, Moore and Blaisdell.

In precipitation the economy of the zinc dust over the shavings method in labor and supplies is such that its use is being more widely adopted each year, especially at the larger plants and new installations.

Altogether, it may be said that each year sees great increase in the variety of ores successfully treated by cyaniding, and especially the silver and silver-gold ores of Mexico.

Miscellaneous Processes.

The more usual ore-dressing processes are the foregoing, namely, water concentration and cyaniding, either of which may sometimes include amalgamation.

Of the remaining processes it may be said that chlorination continues to have a limited application in the treatment of certain concentrates and also continues to compete with cyaniding in the treatment of certain crude ores, notably in Colorado; that leaching of certain copper ores is still occasionally practised, using either dilute acid or acid ferric salts; that a few dry concentrators of the S. & S., the Behrend and other types are being installed now and then, where no water is available, and that recently the Quinner dry-placer machine is being used to some extent, as, for example, in the Altar desert district of Mexico.

In general, however, it may be said that the special processes, for the most part, center around the recovery of zinc blende from complex materials, usually middling products from wet concentrating mills, containing in addition iron and perhaps copper sulphides, carrying usually some gold and silver, frequently also with small percentages of lead remaining from the wet concentration, some of the gangue material being often of heavy specific gravity—garnet, siderite, barite, fluorite and the like.

Considerable progress in the separation of such materials has been made during the past year, the processes grouping themselves, in the main, under three heads—magnetic, electrostatic and flotation.

In point of tonnage handled the magnetic processes of separation continue to lead, either with or without preliminary roasting; in the former case the iron and copper being the magnetic products, and in the latter usually the zinc. The Wetherill, both belt and rotary, the Dings and the International are the more usual types in use.

The electrostatic process is now represented by the Huff separator, which after being perfected in the separation of zinc and iron sulphides in Wisconsin, has shown good results similarly in Utah.

In flotation the Elmore oil-vacuum process is now giving very fair results in one or two small installations in Mexico, the grade of zinc recovered being particularly good. Its application in this country, however, has so far proved limited.

Several of the various acid and oil-acid flotation processes as used at Broken Hill, including also the Horwood process, have been tried out in America, but so far nothing has developed beyond the experimental stage.

Without doubt the most interesting of all the flotation processes so far is that of the MacQuisten tube, in which the sulphides are mechanically floated upon water by passing through tubes some 8 in. in diameter by 6 ft. long, riffled internally by a rib of triple or quadruple pitch. In point of size 20-mesh material is about the maximum that can be readily floated, elimination of slime and a certain amount of classification being also required. A disadvantage is the small capacity per tube, about 3 tons per 24 hours, and the necessity of passing the material through a series of tubes—perhaps a maximum of six in all—in order to obtain a satisfactory extraction. The chief field would seem to be where water concentration fails, as in the separation of sulphides from gangue of about equal specific gravity—such as garnet, siderite, etc.—and very good results are now being obtained upon such material either as original ores or middling products.

Flat River, Mo.

A New Electric Furnace for Steel Melting and Refining.

By Jon. Härdén, E.E.

The electric steel furnace appears to be slowly but steadily gaining ground in this country (England).

A 1½-ton Kjellin induction furnace has recently been erected in Sheffield for crucible steel work, and has successfully completed its guarantee run. This furnace is especially adapted for producing the highest grade of tool steel and is regarded as a most effective adjunct to a crucible steel plant. It is, however, well known that a furnace of this type is not adaptable for any extensive refining of steel, owing to the refining surface of the bath being small.

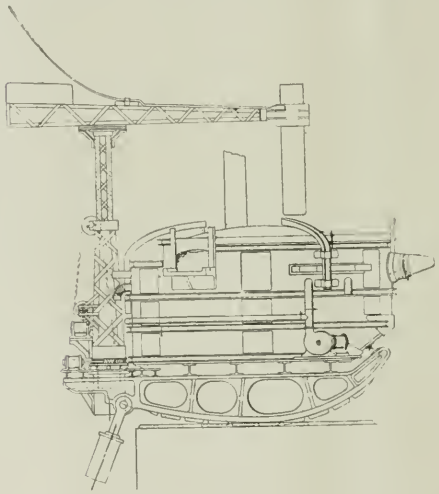

FIG. 1.—VERTICAL SECTION OF COMBINED ARC AND RESISTANCE FURNACE.

It has long been recognized by steel makers generally that although the induction furnace is an excellent tool in the hands of the crucible steel maker a furnace which would permit more extensive refining, and also the construction of large units, at the same time keeping the advantages embodied in the induction furnace system, is much to be desired.

It is because of the comparatively low power factor of larger furnaces of the plain induction type that this class of furnace has not been constructed in large units to any great extent.

In order to overcome this the Roechling-Rodenhauser furnace, which is partly a resistance furnace and partly an induction furnace was designed. A considerable number of these furnaces have been erected and are in operation abroad, giving very good results.

Many steel makers, however, are of the opinion that it would be an advantage if a furnace could allow superheating the slag for refining purposes, but at the same time enable the metallurgist to so regulate the heat of the charge that gases could be expelled without difficulty. At the same time the

perfect circulation of the bath should be maintained, so as to secure a perfectly uniform material. A new furnace designed on these lines, which the inventors call the "paragon" furnace, appears to possess many points in its favor.

As is shown in illustrations, Fig 1, 2 and 3, this furnace is a combination of an arc and a resistance furnace, which makes it very much like an open hearth furnace, and it may indeed be worked exactly in the same manner.

The slag blanket is kept at the desired temperature by means of arcs playing over the surface of the slag while the remainder of the heating power is transmitted to the bath by means of terminal plates, such as are used in the Roechling-Rodenhauser furnace.

The result of this combination is that the slag may be heated to any desired temperature while dephosphorization and desulphurization take place, but the heating effect of the arcs need not be increased to such an extent as to keep the whole charge superheated, which, of course, would tend to overheat the steel immediately beneath the arcs, but a carefully regulated amount of current can be at the same time sent through the resistance plates, thus also heating the charge from underneath.

When the dephosphorization and desulphurization are finished, it may be desirable to alter the gradient of heat in the furnace so that the lower portion of the bath is hotter than its surface, in order to expel the gases more readily. This result is easily obtained by diminishing the power transmitted through the arcs and increasing the power transmitted to the side plates. In fact, it is even possible to extinguish the arcs for a time and keep the bath liquid by means of the side plates, which for this purpose are provided with a cooling device of enforced air.

It is obvious that the metallurgical process is thus considerably facilitated, inasmuch as the metallurgist has the

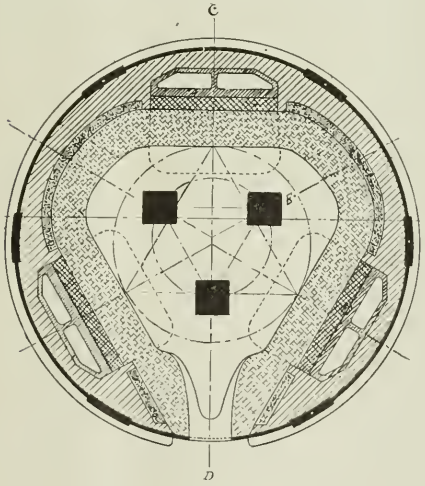

FIG. 2.—HORIZONTAL SECTION.

power of controlling the gradient of heat in the bath at will.

This combination has another advantage, viz, that the electrodes do not require to be of such large section for a given capacity of furnace as would be the case if the total amount of power were transmitted by means of the arcs only, owing to the fact that normally about 50 per cent of the total power is transmitted through the arcs, while the other 50 per cent is transmitted through the side plates. The advantages, therefore, are threefold.

Firstly, the size of electrodes for a given furnace capacity is only about half that of an arc furnace, and consequently with a given electrode section available the melting capacity of the furnace can be nearly doubled.

Secondly, owing to the destructive effect of large arcs immediately under the roof of the furnace, the roof very quickly deteriorates, but in the case of this new furnace the roof is not subjected to such severe strain owing to the reduced size of the electrodes and to the smaller amount of power transmitted through the arcs, therefore the maintenance of the furnace costs less and the roof lasts longer.

Thirdly, the control of the load factor of the furnace is

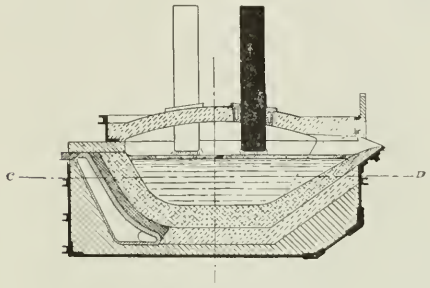

FIG. 3.—VERTICAL SECTION.

better because the current flowing through the resistance plates is a perfectly steady one, whereby the heavy current fluctuation otherwise caused by large arcs is compensated.

The result of this is that no special machinery is required either for compensating for the lower power factor of a true induction furnace or designed with a large flywheel effect, as in the case of a simple arc furnace, on account of its fluctuating load factor. Standard machinery and standard transformers only appear to be necessary, which, of course, decreases the first outlay for the plant, and under the circumstances may prove to be almost a deciding influence.

The power consumption per ton of steel should also prove more economical by means of this combination, as the high temperature of the steel is only required during desulphurization, it being well known that dephosphorization does not require such a hot slag as desulphurization, and it follows as a logical sequence that the higher the temperature of the steel for any length of time the greater also the heat losses during the process; in view of this, the total melting and refining process should be more enconomical with this combination.

It, therefore, appears that the type of furnace includes several of the advantages of the induction furnace, viz, a good circulation of the charge, inasmuch as it is heated from below as well as from above, and a high load factor.

No electrical apparatus, in the ordinary sense of the word, seems to be an element of the design of this furnace, because the power supply transformers may be situated in an adjoining building protected from dust and injury.

The low voltage current only requires to be transmitted to the furnace by means of insulated bus bars and cables.

The regulation appears to be simple, as if the furnace is operated direct from a generator the field rheostat controlling the current to the generator is all that is required; or, if transformers are used in connection with an existing power supply, so-called regulating transformers with interchangeable terminal steps are employed. In fact, comparatively little regulation in this respect should be found necessary, because the current in the arcs ought to be easily regulated by altering the length of the arcs, while the current in the resistance plates is more or less automatically regulated by the condition of the charge.

The author is informed by the owners of the patents, Messrs. The Grondal Kjellin Company (Ltd.), that furnaces of this type will shortly be tried.

Review of the Metallurgy of Copper in 1910.

By L. S. Austin.

Conveying and Transmission.

The belt conveying system at Cananea, which at first presented difficulties in operation, is now in continuous use. It is ideal in theory and it costs only half of any other effective system. R. R. Moore states that the conveying belt, as used at Garfield, has stood the wear and needed but little repair, and the system is now in satisfactory operation. It appears that when installed by engineers experienced in this special line and afterward reasonably handled the conveying belt is durable and smooth in operation. The management of the International Smelter at Tooele, where this system has been installed, is also apparently of this opinion.

In general, in feeding the blast furnaces, where the charge and fuel are weighed, the charge-car is commonly used. Of them all the Hodges car used at Granby works most rapidly and effectively. The load of the car can be adjusted to the condition of the furnace both as to quantity and position and can be dropped where desired. In those systems where the car delivers at the long sides of the furnace it is shot in more at random, and this is apt to show itself in irregularities on the surface of the charge, in more hanging up and in more overfire.

In Mexico, at the plant of the Tezuitlan Copper Company, Mr. Cyrus Robinson, the constructing engineer, convinced of the importance of a uniform charge both in the size of the ore as well as of its composition, takes every precaution to assure this. There are two lines of wire-rope tramway, one of 15 tons hourly capacity carrying limestone to the mouth of the mine, the other of 45 tons capacity taking both ore and limestone to the smelter. Storage is effected in steel bins 40 ft. high and 25 ft. diameter. There are five bins at the mine and twelve at the smeltery having a combined capacity of 3000 tons. The bin bottoms are of rocks dumped in to form the slope which is then covered by rails set at an angle of 45°. These cost but half what a rectangular wooden bin would come to. The ore is delivered to each of the bins in turn to secure even distribution. Finally it is drawn off into a large charge-car and the coke is added. There is an overhead feed-hopper of 65 tons capacity into which the car drops its load. This hopper is divided into partitions to half its depth. A row of gates handled by hydraulic cylinders enable any gate to be opened where desired, so that the ore is dropped where the furnace most needs it, thus securing more elastic feeding conditions. Ordinarily this is done by dumping as seems best into the side doors of the furnace and to some extent (though seldom done) by trimming the charge.

Roasting.

This is now largely done in one or another type of the McDougall roasting furnace. These furnaces have been improved in mechanical details. Some attempts have been made to do away with the water cooling, or at least to minimize its abstraction of heat from the charge. At one plant the rabble blades are slipped over the rabble arm and can be readily slipped off when they fail. But besides this the bladeholders have been shaped so that the flue dust lodges as a layer on them, so preventing the abstraction of heat. As a result less cooling water is used, the arms are preserved and the output of the furnace has been increased. At one of the larger plants the concentrates, carrying 25 per cent copper, really need but little roasting for reverberatory treatment. They are accordingly thrown upon the lower hearth of the roasting furnace, where sulphur is eliminated and where they become hot, and so in suitable condition for the reverberatory smelting to follow.

The dropholes of the McDougalls by which the ore falls from floor to floor are set opposite the sidedoors. Here the ore sticks to the brick work and is hard to remove. This brick surface has been replaced by iron plates and from them the accumulation can be easily barred off. R. R. Moore in his article on reverberatory practice speaks of brackish water as causing scaling of the water surfaces and pipes. The remedy for this would seem to be to use a good quality of water over and over by putting in a satisfactory water-cooling tower.

Reverberatory roasting produces more sulphuric anhydride than blast roasting, and we find the plants using the McDougall furnace successively putting in brick offtakes because of the short life of the sheet-iron outlet flue.

Reverberatory Smelting.

To get rapid melting of the charge in the reverberatory furnace we must burn the coal rapidly. But the gases escaping at the throat should be at least 1100° C. or at the melting point of the slag. Otherwise we encounter the difficulty experienced at first at the Garfield Works when the draft was poor, viz., the setting or crusting of the slag at the front end of the furnace. But with hot gases the question arose how to utilize the heat of these gases and this has been solved generally by using it to produce steam for power purposes.

In open-hearth steel practice the problem has been differently solved, that is by recuperation, by which the hot gases go to a brick checker work and upon reversal of the current air is drawn through the checker work, which adds thus to the intensity of combustion. In the open hearth the temperature is built up by a series of reversals of draft, so that care has rather to be taken to avoid so high a heat as to melt down the roof of the furnaces. It has been stated that the rate of transmission of heat to the charge or the rate of melting will vary with the square of the difference of temperature between its melting point and that of the burning gases. Thus, assuming the melting point of the charge to be 1100° C. and that of the gases 1500° C., melting will proceed at a certain rate due to the difference of 400° C. If the heat of the gases is increased by 100° C. only, or to 500° C. in all, the rate of melting will be increased in the ratio of 16 to 25, or 56 per cent. Is it not better, then, to adopt the open-hearth idea of utilizing the heat to the best advantage for the object in view rather than to employ it for an ulterior purpose? It reminds me of a similar problem in blast-furnace work. Is it better to effectively briquette flue dust or to so run the furnaces as not to make any?

An advantage possessed by the reverberatory furnace over the blast furnace is that the charge can be greatly varied in composition and yet good work be done. The work may be slower, but so long as the slag flows it will be clean. On the other hand, in the blast furnace a viscid slag eventually refuses to issue from the taphole and the furnace "freezes up."

Another advantage is that flue dust is made only at the time the charge is dropped. So little is the loss in this way that no damper is closed at the time of dropping. The passages to the main flue in ordinary practice are large and open and there is little accumulation of dust to interfere with the draft. At Great Falls, where the regenerative open-hearth furnace has been tried, it is claimed that the checker work has been partly closed by accumulating dust. This difficulty should be overcome by a design such that the dust can be removed as it accumulates, and so that the regenerators can be repaired without serious dismantling.

The tendency to-day in copper mining, exemplified in the porphyry coppers, is to handle lower-grade ores that necessarily require concentration. It is these concentrates, too fine for treatment in the blast furnace, that seek an outlet for treatment by the reverberatory. To obtain tonnage in the latter furnace its length has been increased step by step until now a furnace 100 ft. long appears to give the greatest satisfaction. To retain the heat the walls of the furnace have been increased to 30 in. and the roof to 15 in. or 18 in. thickness. So heavy a roof, however, limits the width of the furnace to about 20 ft. and smelting area must be got by increase of length.

The practice to-day seems to confine itself to dropping the charges near the firebox end and to depend upon the charge spreading out gradually owing to its tendency to flow while hot and fine. It accordingly floats slowly toward the front of the

furnace, melting as it goes and dropping out its burden of matte as fast as the matte forms. The result is a cleaner slag. It appears probable that this practice has come about because the heat was so rapidly abstracted from the burning gases by the charge that the fire end was the only effective place for the melting. What might be the effect of regeneration and at the same time of an increased melting area by dropping at other points, as was formerly done, remains to be seen.

The Coal Bed.—In Wales the importance of a deep firebed was long recognized. Clinkers were allowed to accumulate on the grate bars to furnish a bed for the live coals, and by pushing aside the grate bars those clinkers were removed and the fire kept clear. In firing the firebox was filled to the top of the bridge wall and coal was used to close the firehole, thus dispensing with a firedoor. It is along these lines that firing is yet done, generally using the old style of grate bar, which can be so well manipulated. Still, to burn coal rapidly frequent grating should be practised, and this means a loss of perhaps 10 per cent of the fuel as coked droppings. This coked material can be washed for the removal of the ash, or otherwise burned with other fuel for steam making. The depth of the bed may vary from 2 ft. to 4 ft. as experience indicates, but even the deeper beds occasionally burn with holes. The coal is dropped from hoppers and consequently does not get even distribution on the firebed. While doors have been provided for dressing the surface of the fire, it is hard to see its condition in the highly heated firebox and so air may get through to the hearth and thus cool the melting zone. Experiment with the larger furnaces shows that, especially before a new firing, 50 per cent more than the theoretical quantity of air may easily get in, with consequent loss in the intensity of melting heat. It makes one disposed to recommend the down-draft method of burning coal such as Hawley has instituted for boiler firing. Here the upper surface of the coal bed is easily seen and the chance of irregular burning is avoided. Again, the fine, partly burned coal, dropping down through the water-cooled firegrate, is burned on a subsidiary grate below.

At Cananea, where the first reverberatory was fired by powdered coal, the practice was given up in favor of oil, and so satisfactory has been the performance that a second furnace has been installed. One notes that when powdered coal was used the ashes from it accumulated in the outlet flues to the waste-heat boilers and there slagged, at the same time choking the flues. Using oil and allowing for the heat utilized for steam making, the net charge for smelting was 0.43 bbl. to 0.57 bbl. of oil per ton of charge smelted, and this too while melting a mixture of 37 per cent flue dust with 51.5 per cent calcined concentrates.

The Blast Furnace.

While the reverberatory has received a large measure of attention from metallurgists through the year, blast-furnace operation must not be forgotten.

Years ago W. L. Austin laid down the proposition that for real pyritic smelting 65 per cent of pyrite at least should be in the ore. Whether this figure is final or not, at least most of the sulphide ores treated need fluxing, and when this is true then coke must be employed to supplement the heat yielded by the sulphides themselves. A furnace in full operation accumulates hangings or accretions on the walls, but with jackets extending to the feed floor, or to the top surface of the smelting charge, such accretions are easily burned off. Formerly, when the walls were of brick, Austin proposed to prevent such hangings by "column charging": that is, the charge close to the walls was to be of silicious or at least non-agglomerating ore, while within this and constituting the core of the charge were to be fed the sulphides so liable to sinter. I have tried it experimentally, but never have seen it adopted elsewhere.

There is less bosh in copper practice (7 in.) than in lead smelting, as the duty of the furnace in the first case is to do its most active work at the focus near the tuyeres and to complete the melting at the hearth. That this is by no means generally well done is evinced by the slagged tuyeres which must be continually poked to keep them open, and by the very considerable overfire as compared with silver-lead practice. Copper furnaces vary greatly in respect to overfire, and I have noted that when a self-fluxing ore is smelted there is less overfire than where much limestone flux is used. In spite of the endothermic effect of the limestone at the top of the charge, which effect continues up to a temperature of 800° C., the hot top prevails. Slag formation appears to be slow and the fire creeps up and keeps on top. With a fresh charge all looks well again, but before the next one is put in the gases have again risen to 700° C. to 800° C. and the furnace on top is a mass of seething flame, difficult even to look at. Meanwhile the blast is driven through narrow openings produced by the rodding of the tuyeres at high pressure and the hearth, except with excessive fuel, is too cold. We are not to think that this condition is universal. Lower blast pressures, good feeding and suitable slag composition assist in improving these adverse conditions.

Blast furnace jackets are now well built. The inside plate next the fire may be 5/8 in. for stiffness, the outside 3/8 in. Again there are no joints that can be attacked by the molten materials of the furnace, and jackets are made with welded joints especially at the tuyere opening.

The interior width of the blast furnace varies from 48 in. to 56 in., seldom more, and capacity is attained by adding to the length. Even at the Granby Works an addition of 3 ft. to the length is admittedly an advantage. Accretions are more easily removed and the active zone within the end jackets has been proportionately increased by the addition.

Increase in the height of the smelting column has resulted in the saving of fuel, but at the expense of the grade of matte, since the lower column with its greater overfire has caused the elimination of more sulphur.

At Cananea the crude ore charge carries 6.4 per cent Cu and hence, to get a good grade of matte, sulphur elimination is not so important as in the lower-grade ores. The matte fall is then 18 per cent and the matte carries 37.4 per cent Cu. I may add that they claim there is no trouble to keep the tuyeres bright and that the slag crust at the tuyere level is not hard. The tuyeres are barred or cleared out three times daily and are punched every three hours.

Converter Practice.

The great event of the year has been the development of basic copper converting. The process, using a Peirce & Smith basic-lined converter, was introduced at the Garfield plant of the American Smelters Securities Company, and of late these converters have been added to until there are six, five in continuous operation, the sixth as a reserve.

The converters are of the barrel type, 12 ft. diameter by 26 ft. long. The Peirce & Smith patents provide for the expansion of the basic brick-lined interior and for tuyeres that will not be broken by such expansion. The basic process itself is not patentable nor even the lining mixture used. In the United States basic-steel converting has been but little used, but its methods have been thoroughly developed in Europe and are a great aid to those who are now undertaking the conversion of copper matte.

A converter of the size above described will produce 40 tons of blister daily and will output 1800 tons to 4200 tons of blister copper on one lining with minor repairs at the tuyere region. As will be readily understood a low-grade copper matte presents no difficulty in treatment, so different from the case with the acid-lined converter. Within the year the Yampa smelter found it more profitable to sell matte to the Garfield works than to treat it locally. This matte was of too low grade to treat in the acid converter. Later on the Yampa plant was abandoned altogether and the mine output of 600 tons daily turned over to the Garfield works. When the latter plant lost the treatment of the Utah Consolidated ore they were glad to replace it with Yampa ore even at a low treatment rate.

To go back to basic converting: The Anaconda company has,

since last spring, been trying it out in ordinary converter shells with a high degree of success. They use as before the Repath independent tuyere and take up expansion by the use of wooden liners inserted in an occasional longitudinal joint. Around the tuyeres in place of the brick lining comes a packing of basic material with a suitable binding. In this way rapid work is done and the lining is comparatively stable and tight as against air leakage.

The apparent advantages of basic converting are many, especially for a new plant. Since the converter shells are not lifted by traveling cranes, and only such cranes are used as are necessary for handling the ladles, the superstructure can be made lighter, or much handling effected without the use of cranes. We thus do away with the detrimental effects of the sulphur fumes on the crane man.

While time is lost in operating a basic converter, such loss is less than with the acid-lined one.

Silicious ore can be freely used without needing clay or clayey slime as a binder, but at some plants such use is desirable because there is plenty of clayey slime made at the nearby concentrating plant.

The lining department and its machinery and upkeep, with the force needed for lining, is saved; there is but little drying out of linings required.

There are certain disadvantages in operating, but they are being overcome with greater knowledge.

In connection with the above, Arthur M. Day has developed a process, the outlines of which are not yet forthcoming, by which it has been possible at McGill, Nev., to produce slags running as low as 10.2 per cent SiO_2 and as high as 77 per cent FeO, or indeed any grade of slag desired. It can be readily seen that the quantity of slag is thus largely diminished, and in fact the whole process is hastened. On the other hand, in the acid-lined converter, the life of the silicious lining is correspondingly lengthened.

The Smelter Smoke Problem.

Copper smelting works have received severe lessons by disregarding the emission of smoke resulting from roasting and smelting the ores. Offensive as are sulphurous-acid fumes, the damage inflicted has been largely due to the presence of small quantities of sulphuric acid which has formed sulphates, to arsenic and particularly to solid particles of flue dust.

A variety of methods have been tried at great expense to overcome the difficulties, and the most successful has been the bag house proposed and tried 25 years ago for the saving of lead furnace fumes. When made of cotton the bags last but a short time if there is any SO_3 present in the gases, and even woolen bags have too short a life. The problem has been how to dispose of the comparatively small quantity of SO_3 to render it innocuous. This has been accomplished at the United States Smelting Company works in Utah by neutralizing the sulphuric acid by means of zinc oxide admitted to the flue where the escaping gases travel.

The Cottrell process of electrostatic precipitation of the dust is also making headway. In a small unit it has given satisfaction and now we learn that it has been worked up to a successful issue at the Coram plant of the Balaklala Copper Company. A single unit consists of a chamber 10 ft. x 10 ft. with a hopper bottom for the collection of the fallen dust. Within the chamber is a series of positively charged bars set between iron plates. These bars are made of two copper wires covered with strands of asbestos. The bars carry a current of high potential and give a positive charge to the dust particles which precipitates them on the low potential bars of iron. The plates are then jarred to shake the dust thus collected to the hopper bottom.

Salt Lake City, Utah

The Camp Bird, Ltd., Ouray, Col., treated during the month of October, 1910, 6827 tons of ore, producing 7383 oz of bullion and approximately 716 tons of concentrate. The statement for that month shows $109,000 applicable to profit.

A New Form of Electrode.

By A. Mahlke, Ph.D.

In this journal a number of articles has been published about the heat losses through the electrodes in electric furnaces. In the discussion of this object a point has been overlooked which might be of some importance in practice. The electrodes which were used in the investigations for determining the heat losses had a much smaller cross-section than the furnace. Consequently the current density in the furnace charge near the end of the electrodes (see Fig. 1) was much greater than in the interior of the furnace further away from the electrodes. The reason is, of course, that most of the lines of current start from the end of the electrodes, because the electrode resistance is much smaller than the resistance of the furnace charge and the current passes, therefore, through the electrodes as far as possible.

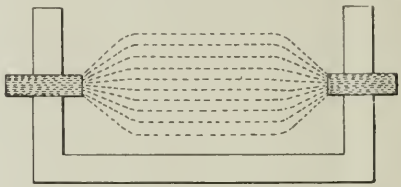

FIG. 1.—LINES OF CURRENT IN FURNACE.

On account of this greater current density in the charge near the end of the electrodes, the charge is at a much higher temperature near the ends of the electrodes than in any other part of the furnace, so that there is always a great difference in temperature within the furnace.

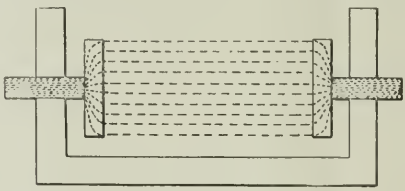

FIG. 2.—MODIFIED ARRANGEMENT.

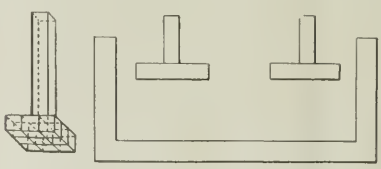
This difference in temperature will exist during the whole process (though decreasing at the end of it), as long as the current in the furnace generates near the inner terminals of the electrodes much more heat than in the interior of the furnace, where the current density is less.

This difference in temperature also causes other inconveniences. The electrodes are heated to a much higher temperature than is necessary for the process in the center of the furnace and are burnt off to a greater degree and cause a greater heat loss than if the temperature of the whole interior of the furnace was uniform. To avoid these inconveniences one should fix at the end of the electrodes big plates of well-conducting carbon material, as shown in Fig. 2, which have the same cross-section as the furnace itself. These plates could be fixed to the electrodes by screws, wedges or any other contrivance made out of carbon, such as are used when short



FIGS. 3 AND 4.—ELECTRODE CONSTRUCTION AND USE IN ARC FURNACES.

electrodes are to be jointed in order to have electrodes of greater length.

By using such electrodes one would have the same current density throughout the whole furnace (see Fig. 2), and so the same amount of heat would be generated in each part if the resistance is the same everywhere in the furnace.

It would be practical to make the carbon plates thick enough to give them a considerable amount of heat capacity so that they can take a good deal of that heat generated in the part of the electrodes between the plates and the walls of the furnace, this part being heated to a higher temperature than the plates on account of the greater current density. But since some portion of this heat is conducted through the plates into the interior of the furnace, the heat loss is diminished as well as the burning off of the electrodes.

For resistance furnaces one could make such electrodes by packing carbon blocks around the end of the electrodes, as shown in Fig. 3. The resistance between the electrode itself and the blocks could be lowered by fixing the blocks to the electrodes with a graphite paste.

While these electrodes would be especially suitable for resistance furnaces, they might also be used for arc furnaces. The big mass of the plates forming that part of the electrode from which the arc arises (Fig. 4) would not get so hot as the thin end of the electrodes now generally used. So the amount of electrode material necessary for the process in the furnace might be decreased, which would be of importance for many purposes. The big plates only would be renewed, while the other parts of the electrodes carrying the plates could be used for many furnace runs.

Progress in Cyaniding During 1910.

BY R. W. GORDON.

So many specially trained engineers and chemists are now engaged on original work in connection with cyaniding that improvements are yearly increasing in number, if not in importance. The employment of educated men on mill work, too, has led to a more liberal policy in the publication of special information, both in the technical press and through constant interchange of visits and experience between cyanide operators. Progress, therefore, is proportionately more rapid as each man can commence his original investigations where his neighbor left off.

Nothing revolutionary has occurred in the cyanide field in 1910, improvements being chiefly confined to details, but the first mill using a continuous process throughout was placed in operation during the year, and the same mill adopted, with reported success, chemicals for aiding cyanide in the dissolution of values from a sulpho-telluride ore.

For fine crushing and grinding, especially on hard ore, stamps followed by tube mills have been specified in practically all the new mills, and much has been done in the past year, both in this country and South Africa, to properly apportion the work between them. Coarser and coarser material is being fed to the tube mill, and the point at which the cost of power and pebbles outweighs the initial expense and maintenance of stamps is a most important question, and one which must be solved for each installation.

If it were not for the nuisance of elevators and screens, rolls, crushing either wet or dry, would often replace stamps ahead of tube mills, and several plants using rolls and tube mills will be placed in operation early this coming year.

Chilian mills have held their own for crushing moderately soft material, and are attractive as occupying less space and costing less per ton for installation when foundations, bins, and buildings are considered. At the Goldfield Consolidated Mill a notable installation of these mills was made in 1908-9, where six Chilian mills were introduced between 100 stamps and six tube mills for intermediate grinding. At a comparatively low expense and without any addition whatever to the bins or building the capacity of the mill was materially increased. No data have been published to show whether any great economy has been effected by stage crushing and the elimination of the final undersize between each stage, but in a mill of this size stage crushing would certainly appear to be advantageous, for conditions could never be more ideal.

Considerable discussion is still taking place in the technical press between advocates of tubular and conical mills. So far no reliable data has been produced to show that conical mills are more efficient than the standard tubular type. The former seems to have given entire satisfaction in some places, and in others, again, particularly where a comparison has been possible, it has been discarded and replaced by the tubular. The use of steel rods instead of pebbles as a grinding medium in tube mills has been suggested and tried out on a small scale, but no millman has yet been induced to make a working test. Rather extravagant claims are also made that by the use of these rods material can be taken direct from the crusher and reduced to the necessary fineness at one operation, which is certainly a desideratum.

The use of shorter tube mills has been urged with the idea of removing as quickly as possible material which is already fine enough and returning the oversize to the feed end for retreatment. On the other hand, at El Oro a special attachment was recently added to the discharge end to prevent the oversize from leaving the mill. It would seem as if the accumulation of oversize at one end might have the effect of causing unequal liner wear.

It is now thoroughly understood that the efficiency of a tube mill depends almost entirely upon the consistency of the feed, excessive moisture being detrimental in every way. A dewaterer, therefore, as much as a classifier of coarse and fine material has become an essential part of tube-mill equipment. In individual cases, the Bayliss and Akin classifiers, which operate on the screw or worm principle, first used by George Moore at Mercur in 1903, have been installed for this work, and the Caldecott diaphragm cone is also used, but the Dorr classifier in its improved form was generally specified in 1910 installations, and appears to have given entire satisfaction.

In the year 1909 the continuous movement of pulp through a series of agitators was first adopted at the San Rafael mill in Mexico, after experiments on a working scale, in which both charge and continuous agitation were thoroughly tried out. At first thought it would appear possible for a particle to pass through three or four tanks without the necessary period of contact, but practically this chance is proved to be almost negligible and continuous agitation is now being used in many important plants, such as the Liberty Bell, in Colorado, and the Esperanza, in Mexico. By its means objection to the use of very deep air agitators has been overcome, as so little headroom is needed between the points of intake and discharge. Great care must be taken, however, to draw from one tank into the next a pulp having exactly the same consistency as that fed in, otherwise there will be an accumulation either of fine or coarse material. Such an adjustment can easily be made, however, and once made the agitators require practically no attention. This method has been applied successfully to so-called Pachuca tanks, to Hendryx agitators and to other forms of mechanical agitators.

With the objection to great depth removed, the Pachuca tank has become more than ever the favorite form of agitator, largely on account of the removal of all wearing parts from direct contact with the pulp. Among other agitators now in the market might be mentioned the "A Z," lately introduced from Australia, which employs practically the reverse of the Hendryx principle, and forces material from the center along the flat bottom of an ordinary shallow tank and up its sides. Although it consumes considerable power, it presents advantages over other forms, where heavy materials, such as sulphides, require agitation.

Continuous settling having been furnished by the Dorr thickener, and continuous agitation being also an accomplished fact, the need for a simple continuous method of separating valuable solution from valueless solids after agitation, or rather displacing the former by water, became more apparent.

Years ago, and before the invention of modern mechanical filters, an ingenious method of continuous dilution or decantation was evolved by John Randall in a small wet crushing mill near Deadwood. Intermittent decantation with its volumes of solution was then the order of the day, when Randall conceived the idea of reducing the amount of solution in circulation by using one solution only, and that a mixture of his final barren solution and water washes. This solution he continuously decanted off the final tank, used it for diluting the preceding one without return to the stock tank, again decanted it, and again used it for dilution until the first tank was reached. It thus gradually became enriched sufficiently to be worth precipitating, while the pulp moving in the opposite direction became impoverished. Randall's scheme worked perfectly on paper, but, unfortunately, the mechanical means then available for settling and pumping were unsatisfactory. It remained for Dorr to adapt the idea successfully to a series of his thickeners, first at the El Palmerito mine in Mexico and later in this country.

A simple continuous filter which will give perfect displacement is still badly needed, however, as continuous decantation yields tailings high in moisture and also, unfortunately, high in cyanide, especially if strong solution is in general circulation in the mill.

The Moore filter suit still drags along, and it is an open question whether Moore will eventually control the whole vacuum-filter field, as he undoubtedly deserves to, or whether it will be thrown wide open.

Merrill's pressure filter is being installed at the new Gertrudis mill, but it requires special conditions, whereas movable or stationary vacuum filters are applicable everywhere and give uniformly good results. Various forms of continuous revoluble filters have been placed in operation during the year, but so far they are too complicated to be widely adopted, and none of them compare with the intermittent vacuum filters in the displacement of valuable solution. South Africa has at last followed this country in adopting vacuum filtration instead of intermittent decantation, and we presume will shortly be trying out continuous agitation and decantation also.

Separate treatment of sand and slime is seldom considered in a modern mill, but mention must be made of a novel method in use at the new Portland mill, in Colorado. There separate treatment is used, but the commercial values in the sand are in solution when the classifier is reached, and all that is needed is a wash.. The thickened sand from the classifier is, therefore, led through a second classifier—or, more properly, a dewaterer—containing barren solution, and from there, through a third containing water, to the dump.

The possibilities of the Clancy chemical process have become more and more apparent, and the reported success of the Crow-Tippet method at the Portland mill has but whetted the appetites of producers of sulpho-telluride ore for a mill operated under straight Clancy principles. Such a mill will shortly be built in the Cripple Creek district, and a satisfactory economical outcome would appear highly probable since the Clancy claims have been published. The field for such a process is large and profitable, as quantities of ore are known to exist containing values in sulphide form, but are too low grade to afford roasting. The operation of the first plant will, therefore, be watched with much interest.

For precipitation in the larger mills the use of zinc shavings seems to have given place almost entirely to zinc dust, the press generally installed being the Merrill triangular press, which was perfected at the Homestake. One great argument in favor of the use of a zinc dust press is safety of the precipitate, either in case of fire or of light-fingered employees.

On the whole, the year 1910 was well spent by the cyanide fraternity. Costs were reduced, tonnage increased and more bullion produced by the cyanide process than ever before.

A Vertical Magnifier

By H. M. Boylston.

The little instrument[1] illustrated in Fig. 1 was devised in this laboratory as the result of a long search for a simple, convenient and inexpensive means of measuring the impressions made in metal specimens by the Brinell ball test for hardness.

It consists of a doublet lens made up of two plano-convex lenses having a combined focus of 38 mm. and adjusted in a cylindrical mount about 3 in. high and open at the bottom, as shown in the figure. Provision is made for vertical illumination and a small scale is added for measuring small distances accurately. The focusing glass used by metallographists makes a satisfactory basis for constructing the instrument, the lenses in this being specially corrected for flatness of field and sharpness of focus.

A brilliant illumination is obtained by inserting a plain glass reflector *G* in a slot cut in the cylindrical mount at an angle of 45°, one side of the cylinder being left open to admit light from any convenient source (daylight, incandescent electric lamp, Welsbach gas burner, etc.). The path of the light from its source to the specimen to be measured or examined is indicated by arrows in the illustration.

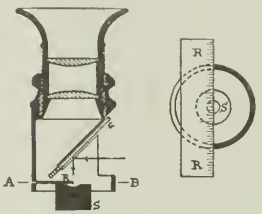


FIG. 1.—VERTICAL MAGNIFIER.

A thin steel scale *R* with proper graduations on one edge is inserted near the bottom of the cylinder in a slot cut for that purpose and is adjusted so that the graduated edge corresponds to a diameter of the cylinder.

The instrument is held in one hand with the opening directed toward the source of light, while the specimen *S*, with impression uppermost, is held against the steel scale with the other hand in such a position that the scale corresponds with a diameter of the circular edge of the impression, one of the graduations of the scale being set tangent to an edge of the impression. The diameter of the impression is then easily read off on the scale which with the impression itself has been magnified considerably by the lenses of the instrument. A scale graduated to 0.2 mm and hence easily read by interpolation to 0.1 mm has been found very satisfactory, since no greater accuracy than this is warranted; for the impressions obtained in this test often are not perfectly circular and the lip of the impression is often rounded instead of being sharp. Steel scales graduated to 0.1 mm can be obtained, however.

Although designed primarily for the purpose just described this instrument has many other uses. It can be used to great advantage in examining fractured surfaces, or for examining the polished surfaces of metallographic specimens for flaws in the polishing, or for minute blowholes. It will also lend itself readily to any case where a low power magnifier is needed or where small distances are to be measured rapidly with the degree of accuracy already indicated. It is hoped that the magnifier will be found useful in many cases, in the machine shop, for instance.

The focus of the instrument may be adjusted within limits for large specimens, in which case the scale is removed from the slot and laid directly on the object to be measured, the magnifier being placed above and against the scale.

Metallographic Laboratory of Harvard University.

[1] Another somewhat less convenient, but fairly satisfactory device of this sort is described on p. 53, "Laboratory Experiments in Metallurgy" by Sauveur and Boylston.

Metallurgical Progress in Utah and Nevada During 1910

BY ROBERT H. BRADFORD

Salt Lake City is conceded to be the most important smelting center in the United States. The tremendous ore supply of Bingham, Park City and Tintic gives a combination of easily smelted mixtures and has justified the building of exceedingly large smelting plants near Salt Lake City. The favorable position of this region as a railroad center enables the smelters to draw large supplies of ore from all parts of Utah, from Nevada, Idaho and even from California. The ore supply is more diversified than anywhere else in the Union.

Large custom smelters with their keen competition for custom work have given smelting rates more favorable to the seller than those obtaining elsewhere.

The large companies maintaining custom plants in this region include the American Smelting & Refining Company, the United States Smelting, Refining & Mining Company, the International Smelting & Refining Company.

The Murray plant of the American Smelting & Refining Company has been operating during the year at somewhat reduced capacity as has been common to most of the lead plants of this company. The improvements in the pot roasting process have reduced the cost of roasting the sulphide ores and have given very desirable materials for blast furnace smelting. Record runs for lead blast furnaces of dimensions 46 in. x 168 in. have been made during 1910. The greatest tonnage for a single day was 318 tons of ore and flux, exclusive of fuel and returned slag. Average daily tonnage for one furnace for a whole month was 280 tons. These figures show the highest tonnage yet reported from any lead smelting plant.

The Garfield plant, a copper smelter, has operated on increasing ore supplies during the year. The concentrates from the gigantic concentrating mills of the Utah Copper Company, from the new mill of the Ohio Copper Company, along with ores and concentrates from numerous mines of the surrounding country have taxed the reverberatory and blast furnaces to their limits.

The basic lined converters of the Peirce & Smith type have done excellent service. By means of the process using basic lined converters the cost of converting at Garfield has been notably lowered. The converter shell is 23 ft. long by 10 ft. in diameter. Next to the shell, along the bottom, is a lining of ordinary fire brick varying in thickness from 4 in. to 13½ in. This lining is thickest along the bottom and becomes thinner as it rises to the sides. Inside this lining is the basic lining of magnesite bricks. The circular throat is at one end. Matte and silicious ore are charged through the throat. Thirty two cast-iron tuyeres are provided, each with special valve and flexible hose connection to the air main. An opening called the breast opposite the tuyeres provides for the removal of the slag and metal.

The initial charge of matte consisting of four or five ladles of matte (40 tons) is poured in through the throat and about three tons of dry silicious ore are added. The blast is introduced and the converter rotated until the tuyeres are well below the surface of the charge. When the blow is well begun the blast pressure reaches 10 lb. to 12 lb. per square inch. When the silicious ore has been fluxed the slag is poured and additional amounts of matte and ore introduced. The operation is repeated and continued until enough "white metal" is formed, when the addition of matte and ore ceases and the white metal is blown to blister copper.

Care is taken to thoroughly dry the silicious ore before charging it into the molten matte to avoid explosions.

At the United States lead smelter at Midvale the arsenic plant is of interest. The blast furnace flue dust collected at the bag house is returned to two Brinton roasters having rotating hearth and stationary rabbles. Each furnace has capacity of 10 tons per day. The dust heated to redness in this furnace is in large part volatilized. The residue from the hearth goes back to blast furnace. The fumes from the Brinton furnace consist principally of arsenious oxide (As_2O_3). The sublimed arsenic product is collected in zigzag flues built of brick masonry. The product from these flues is taken to a reverberatory furnace and revolatilized or resublimed, the fumes again collected in zigzag flues. The product from the second set of flues is practically pure As_2O_3. It is taken from the flues in cars and transported by a monorail tram to the packing room, where it is packed in barrels with capacity of 400 lb.

Many improvements in converter roasting are being perfected at the United States plant. Much flue dust is being sintered into a form suitable for blast furnace treatment. None of the ores fed into the rectangular converters receives any previous roast. Thin layers of ore and short time for roasting a charge have increased the capacity of the roasting plant. Careful mixing and moistening of the ingredients have assisted materially in the converter roasting.

The International Smelter at Tooele, Utah, was put into commission on July 25, 1910. This plant is entirely new and thoroughly up to date. Construction work was commenced Dec. 9, 1908, just 19½ months before the first furnace was blown in. Considering its extent and the massive construction this plant holds the record for speed of construction.

The smelter was built primarily to treat the ores from the Utah Consolidated Mining Company's mines at Bingham and the South Utah mines at Newhouse, Utah, but is provided with capacity to treat also much custom ore. The Highland Bay smelter at Murray originally treated the Utah Consolidated ores, but this plant was closed down as the result of injunction proceedings brought by the farmers of Salt Lake County.

The ore is sent from Bingham to the International by a Bleichert aerial tramway four miles long built over a very rugged route. The tramway has a capacity of 125 tons per hour. The receiving bins at the smelter are of steel with a capacity of 10,000 tons. The ore from these bins is conveyed to the sampling mill by belt conveyors, where it is crushed and sampled. From the sampler the ore is conveyed by belt conveyors to the receiving bins at the McDougall roasters. From these bins the ore is again conveyed by a belt conveyor to the charge hoppers of the McDougall roasters. In transit from the bins to the roaster plant the ore is weighed automatically as it passes over a Blake-Denison continuous weighing machine.

The roaster plant contains 16 McDougall furnaces of 45 tons daily capacity. From these furnaces the ore drops into hoppers arranged directly over the tracks of the electric tramming system for transportation to the hoppers of the reverberatory furnaces.

Five coal-fired reverberatory furnaces 19 ft. x 102 ft., with a grate area of 7 ft. x 16 ft., are provided, each with a capacity of 300 tons in 24 hours on natural draft. The flame from each furnace passes through a 746-hp Stirling boiler and develops 600 hp of energy. The slag is skimmed into slag cars of 225 cu. ft. capacity and hauled over the electric tramming system to the slag dump. The matte tapped from the side of the furnace runs through launders directly into the converters.

The converters are of the barrel type 96 in. x 150 in. and are operated electrically. A 60-ton electric traveling crane is provided to serve the converters. The casting room has a 30-ton crane and there are two small 12½-ton cranes used to transfer the slag from the converters directly to the reverberatory furnaces in the molten condition.

The metallic copper is poured into the casting ladle and cast into bars ready for shipment to the refinery.

The following notes were made and published* by the writer on the occasion of the visit of the Utah Society of Engineers to the International smelter:

*Salt Lake Min. Rev., Nov. 15, 1910.

A striking feature of the new International smelter as observed on the trip was the massive steel construction everywhere apparent giving large roomy buildings with high roofs affording excellent ventilation. Surely the idea of supplying the workmen with good air is worked out successfully.

The means of transporting materials about the plant was a most interesting feature. The standard broad gage tracks for the electric locomotives allowing for the movement of large railroad cars anywhere about the works, the free use of the belt conveyor with its automatic tripping and weighing devices, the unusual adaptation of the electric traveling cranes for ladles and converters provide an ease and economy of movement unsurpassed in modern smelting practice.

The careful sampling along with the exact weighing of materials makes it possible to check one department against another and thus place the responsibility for any losses due to careless operating at any stage of the smelting process.

The plant has an excellent location, being near the mines supplying most of its ore, the mountain range intervening being of little consequence, thanks to the aerial tramway; also near two through railroad lines and yet away from the agricultural districts. The gently sloping site, allowing for extensive building construction on any one level, and yet with enough relief for the materials of the smelting operations to be moved horizontally with but one lift, combines the good features of the terraced and the level site. The extent of the grounds laterally will allow of the addition of extra units with ease.

The simplicity of the process by which they pass from the mine ore to copper bullion illustrates the tendency of most recent commercial practice, but three operations being required, namely, roasting, smelting and converting. Contrasting this with the Welsh method in operation in Wales when that country was looked to as the leader in copper smelting, we see the operations cut to one-third. This Welsh method involved nine different operations, consisting of partial roasting, smelting, another roasting, a second smelting, etc., each process consuming fuel, material and energy far out of proportion to the advance of the resulting product toward the copper bullion desired. The "conservation of resources" is everywhere apparent at the International. The sulphur of the ore in the McDougalls furnishes all the heat for roasting and part of that needed in smelting. The roasted ore is not cooled, but charged hot into the reverberatories where it receives the additional heat necessary for fusion. The fuel of the reverberatories gives heat for the fusion and for the generation of steam more than sufficient for all power about the works. The matte in the converters is kept sufficiently heated by the burning of its iron and sulphur by the air forced into it so that the metallic copper is taken out well above the fusion point, allowing it to be poured slowly into the molds ready for market.

Cyaniding.

Utah enjoys the distinction of having the oldest cyanide plant in the United States. The Mercur mill was the first to try out the McArthur-Forrest process in this country. The Mercur mines are still producing handsomely and the ore, while not treated now in the original mill, is still responding to the cyanide process in the improved De La Mar mill now owned by the Consolidated Mercur Gold Mining Company.

Until the beginning of the present year the roasted ore was not classified and treated in the filter plant, but was kept separate from the oxidized ore. Now the roasted ore is mixed with the oxidized before the cyanide solution is added and all ore is classified and either leached or filtered according to its fineness.

An increased extraction is claimed from passing air up through the leaching pipes into the sands at intervals during the leaching. Experiments are being carried out with a view to using zinc shavings instead of zinc dust for the precipitation of the gold.

The company is now retreating old tailings to the extent of 100 tons or so per day. The supply of base ore from the mine is amply sufficient to keep the mill supplied with the 700 tons per day required.

The old tailings dump at Manning, four miles from Mercur, is being treated by the Manning Leasing Company. These tailings from the old Mercur mill carry $2 to $2.50 gold per ton. About $1 of this value remains in the tailings after present treatment. The company is using the Holderman filter process very successfully. It treats 100 tons of tailings per day at a cost of 75 cents per ton. The tailings from the old dump are conveyed to bins and sluiced with cyanide solution from bins into Chilian mills. All material passes through 18-mesh screen and is run by gravity to Holderman tanks fitted with filter leaves. The solution runs by gravity through canvas leaves and then to the gold tanks. Wash water or weak solution is run into tanks for 16 hours and the pulp is then sluiced over the dump. All clear solution from filter leaves goes to gold tanks and again through Holderman leaves to zinc boxes. The gravity filter leaf in the gold tank does excellent service, as is evidenced by the crystal clear solution as it enters the zinc box.

The Daisy Combination mill at West Dip, five miles west of Mercur, is milling 140 tons of ore from the company's mine. The process employed here is much the same as that used by the Consolidated Mercur mill.

The Utah Leasing Company, operating the Old Telegraph Mine at Bingham, has built a 50-ton cyanide mill to treat the silicious ore that the former company had left in the mine owing to high penalties for silica imposed by lead smelters. The ore is first crushed by a Ferraris-Blake crusher to ½ in. in diameter, then fed by an automatic plunger feeder into a tube mill. Cyanide solution is added as ore enters the tube mill. From this mill the pulp, after addition of more solution, is classified. Sands return to the tube mill. All slimes are agitated in Pachuca tanks for 36 hours. Pulp is then transferred to 100-ton settler. Thickened pulp goes to Kelly press and all clear solution to zinc boxes. The cost is $1.50 per ton for an extraction of 82 per cent.

Nevada.

During the years 1906 and 1907 the Western mining States enjoyed a period of prosperity previously unheard of. No one camp or no two or three camps were responsible. The entire mining West shared in the prosperity. If any State received more attention than another Nevada was that State. Her mountains were hurriedly prospected, with most flattering results. Many rich gold camps sprang up and the gold and silver ore taken from the surface outcrops created such a stir that it became common understanding that a gold prospect in Nevada was more attractive than such a prospect anywhere else. In fact it was not uncommon for the prospector to succeed in selling his claims simply because he could show they lay in Nevada. Purchasers seemed willing to buy geography.

It is not strange that many "wild cat" schemes were floated and that many investors lost their money. Nevertheless the fact remains that the gold and silver properties of real value opened up at that time and later show a most wonderful richness, and Nevada is now and will continue to be one of the foremost States in the production of the precious metals.

During the past year the State has furnished the mints with gold bullion in advance of any previous year. The mines in all parts of the State have added their quota, making a total that is enviable. While the large metallurgical plants like those of the Goldfield Consolidated, the Tonopah Mining, the Montana-Tonopah, etc., have operated regularly with large monthly shipments of gold and silver bars, the metallurgical feature of striking importance is the erection of the many smaller mills throughout the entire State. In many cases transportation facilities have not warranted the shipping of ore to custom works at any considerable distance and individual mines have built their own mills. Where the production of the

small mine would not justify the building of a mill, a number of small producers have contracted a certain small tonnage each to a custom mill to be installed near at hand. Thus 10-stamp mills, 20-stamp mills, 30-stamp mills have been put into commission or contracted for very widely.

The metallurgical progress of recent years has made this possible. The recent development in cyaniding silver minerals, the improved methods of getting the gold ore finely crushed and cheaply filtered have assisted in making possible the treatment on a small scale of the gold and silver ores of the State.

It will be impossible to give even a brief description of the mills put into commission and those being erected during 1910, and I shall attempt only to give some data regarding a few of them. In many instances the gold is coarse enough to be readily caught by the amalgam of the plates. Where the ore is in condition for a good extraction to be obtained by amalgamation alone, stamp milling with apron plates is all that is employed. In other cases the coarse gold only is amalgamated and the fine cyanided. Where the gold is partly in combination with sulphides present, concentrating machinery is also employed and two marketable products are obtained, bullion and concentrates. The concentrates are often shipped to the smelters, but may be profitably treated by special process at the mill. Cyaniding after fine crushing with long time and strong solution is effective in extracting the gold from the concentrates, and this process is resorted to at some of the mills. Then chlorination after roasting is employed with the concentrates at the Goldfield chlorination mill with excellent extraction.

The 60-stamp mill of the Tonopah-Belmont Company at Millers has operated upon 220 to 250 tons of ore per day.

The Tonopah-Liberty Mining Company has put into commission its mill at Liberty near Tonopah. The power for this plant is obtained from the Nevada-California Power Company. The all sliming process is employed and the mill is a model of modern construction. The ore passes through a Blake crusher, Chilian mill and tube to be reduced to slime, then a Trent mechanical agitator, combining power and air agitation, and finally to the Oliver filter. The mill has been in commission since Oct. 2 and is treating 130 tons per day.

The 30-stamp mill of the Tonopah Extension Company is treating 135 tons per day, obtaining concentrates to the amount of 40 tons and bullion valued at $45,000 each month.

The Bonnie Clare mill in the Gold Mountain district, Nye County, started up in September prepared to treat the company's ore as well as custom ore, stamp milling, amalgamation, concentration and cyaniding being employed.

The 10-stamp mill of the Nevada Reduction Company at Manhattan is a good type of the small mills recently erected and now building. After the stamps come the silver-coated copper amalgam plates, then the classifiers (in this mill the Dorr is used) giving sands for tube mill and slimes to join the product from the tube mill going to the filter (the Oliver is used here). The gold is precipitated by zinc shavings in the zinc box,

Small 10-stamp mills or mills of this capacity are to be found in operation or building at Rhyolite by the Tramp Consolidated; at Dayton, Lyon County; at Blackhorse by the Amalgamated Nevada Company; near Manhattan by the Manhattan Milling & Leasing Company; near Caliente by the Gold Chief Mining Company; in Esmeralda County by the Gold Bar Company, and at various other localities.

Larger mills ranging from 50 tons to 150 tons capacity are operating or building by a number of other companies, including the Nevada Hills Company, at Fairview, Churchill County; the Rich Hill Company, at Eldorado; the Rawhide Queen and Rawhide Coalition—the Queen mill is now running; the Austin-Manhattan Company, with its dry concentration process with the Huff electrostatic machine; the Rainbow-Amazon Company, at Jarbridge, Elks County, etc.

The Butters cyanide plant in Six-Mile Canyon, Storey County, is closed for the winter. During this time it will be put into first-class condition.

The Bamberger-Delmar 500-ton cyanide plant has been sold to the Great Western Machinery Company, of Denver, who are dismantling and disposing of the plant. The above are some of the mills that have been installed or undergone changes during the year, but it by no means embraces all that might be mentioned.

The Mason Valley Mines Company is erecting a smelter at Wabuska to treat the ores from the Nevada-Douglas and many other Nevada mines.

The mammoth Steptoe smelter at McGill, Nev., has been in full operation and has reached an output of 6,000,000 lb. of copper per month. The cost of smelting is kept down below that of most modern plants. The future of this plant along with the concentration mill of the company is most promising. The shipment of an entire trainload of copper bullion—25 cars of 50 tons each—from the Steptoe smelter to the Eastern refinery will impress one with the magnitude of the company's operations.

Gold and Silver.

Bullion Refining.—The details of electrolytic refining of cyanide precipitates at the Waihi Gold Mining Company, Waihi, New Zealand, are given in the *Aust. Min. Stand.* for Oct. 26, 1910, by J. G. GOODSMAN, who has been identified with the work in every department.

The zinc boxes are cleaned weekly at each mill, where the gold-silver alloy is prepared for subsequent treatment at the electrolytic refinery. The zinc slime is treated with 10 per cent sulphuric acid in wooden vats 9 ft. in diameter and 6 ft. deep. Agitation for one hour usually dissolves the zinc, after which the slime is washed with hot water, the solution decanted and the slime filtered by vacuum pump. The dry slime is then mixed with flux, consisting of 30 per cent of its weight of borax, tamped into iron trays and dried in an oven.

The custom of melting this material in plumbago pots, followed by cupellation of the metal, was abandoned some time ago, but will be adopted again on account of the inherent difficulties in the present system. At present the melting and cupelling are both carried on in a "test," but a great deal of trouble is experienced in getting mixtures which will withstand the action of the borate slag, and that of the litharge and copper oxide. The "tests" now used have a foundation of cemented firebrick and sides of cement 3 in. thick. The absorbent body is well tamped in and allowed to stand several weeks before using.

For use the "tests" are heated in a furnace under good blast and the charge is added with scoops. As soon as molten the "test" is tipped to allow the slag to run off. When all the slag has been run off the first lead is added, which amounts to 10 per cent of the weight of the dry slime. The cupellation is hastened by a blast of air through a tuyère, which drives the litharge over the breast of the "test." When the first litharge is almost removed, the retorted gold from amalgam plates is added, and a second charge of lead, 5 per cent by weight of the slime, making in all 15 per cent of lead added in cupellation. In the other system of melting in pots followed by cupellation only one charge of lead is used, amounting to 10 per cent of the weight of the bar bullion.

The slag from the melting operation and the litharge from the cupellation are reduced in a small blast furnace, and the resulting lead is either refined if rich in bullion or liquated and used again in cupellation. The gold-silver alloy is ladled from the "test" into molds 10 in. x 8 in. x ⅜ in., each bar weighing about 200 oz.

The electroylic plant has 30 cells, each having a capacity of 10 gal. of parting solution, 0.6 per cent nitric acid. In each cell are filter frames holding four of the bullion bars, with the anode terminal on the adjoining edges of the bars. The 4 sq. ft. of cathode surface is a ¼-in. silver slab fitting the bot-

tom of the bath and having a 4 in silver ribbon connection with the cathode terminal. The current used is 100 amp, or a current density of .25 amp per square foot of cathode surface. The voltage averages 0.5 volts, or 3.16 per cell. This figure varies with the temperature of the bath and with the decreasing distance between anode and cathode. The precipitated silver is scraped from under the filter cloths with wooden scrapers, washed to remove acid, melted in pots and cast in bars of 1000 oz., .998 fine. The gold and bullion scraps from the filters are washed through a 10-mesh sieve, the fine gold washed free from nitric acid and boiled for three hours with concentrated sulphuric acid. After another washing the gold is melted in pots and cast into bars of 1000 oz., .997 fine. The silver from the acid solutions is precipitated with salt and reduced with zinc, sulphuric acid being added to hasten the action.

Copper.

The Converter Flame.—The process of copper converting is indicated and controlled largely by the appearance of the flame issuing from the nose of the converter during the blow. The changes occurring are not as easily described as observed. An interesting article dealing with the successive stages of converting as indicated by the converter flame has been contributed to the Institution of Mining and Metallurgy by Mr. Donald M. Levy. The article is published in *Bulletin* No. 74 and is accompanied with reproductions of color photographs taken on Lumière plates, the exposures being made at night in the converter-room at the Washoe Smelter, Anaconda, Mont. The illustrations are excellent reproductions of the various flames, of which four are shown in the original paper.

The first shows the condition at the beginning of the blow, and is a rich red-brown flame due to the coal added, to the burning of iron and sulphur, and partly to the zinc, lead and arsenic in the fume. The flame continues red to red-purple for from two to eight minutes, after which the green flame appears and the slagging stage has properly begun. The green becomes more and more prominent, and after about 15 minutes is a vivid apple-green. This is shown in the second color plate, and is typical of the slagging stage.

The white-metal stage is indicated in the third color plate, where the green has disappeared and flashes of blue appear, resulting in a white-blue flame. At this stage the slag is poured off, and if the converter is too hot it is "doped" or charged with scrap copper.

The second part of the blow, from white metal to blistered copper, commences with a red-brown flame and smoke, but finally thins to a red-purple flame and continues thus to the end of the operation. This is shown in the fourth color plate. The end of the blow is difficult to judge, but is determined by the emission of small shots of hot copper, which no longer adhere to the hood over the converter, but rebound from it.

The green effect during the slagging stage is due to the formation of iron silicate, while the blue flame at the end of the slagging stage indicates that the iron has been slagged and that copper silicate is being formed. These colors are not produced unless the respective oxides are being slagged.

Following are observations made during a complete blow:

Converter A.—Matte charge.

Charged 2:25 p. m.—Flame red.
2:29 p. m.—Green appears.
3:00 p. m.—Green becomes brighter
3:17 p. m.—Vivid green.
3:18 p. m.—Skimmed; no metal reached.
3:21 p. m.—Blue appears in flame.
3:27 p. m.—Flame chiefly blue; converter turned down to skim. Doped

Converter B.—White-metal charge

Charged 4:13 p. m.—Doped.
4:14 p. m.—Converter turned up; flame red
4:16 p. m.—Flame red-purple.
4:18-5:20 p. m.—Flame peach to bronze-purple color

Ore Dressing.

Classification.—Metallurgists generally recognize the great service which Prof. Robert H. Richards has rendered to the industry of ore dressing. They will be glad to study his latest contribution on the development of hindered settling apparatus, which has been published in the November and December, 1910, issues of the *Western Chemist and Metallurgist.*

The causes of loss in concentration are first considered, and then methods of voiding the losses. The author find four ways in which mineral loss may occur: as including grains, as long or flat grains, as fine free mineral and as absolute slime. The treatment of flat, long or included grains will involve recrushing to a size which liberates the maximum quantity of mineral while making the least slime. Fine, free mineral in jig, table and vanner tailings offers the ripest field for improvement in milling, and the object of the present paper is to consider methods for saving this product. In regard to absolute slime, the author is still in doubt whether they can be saved by any means or not.

Free Settling.—The author then takes up four methods of making free settling tests to determine the ratios of quartz and galena which are equal settling. The methods are: (1) by letting clusters of grains settle together; (2) by letting individual grains settle one at a time; (3) by spitzlutte and microscope to get the ratio, and (4) by spitzlutte and photograph to get the ratio. The four methods give nearly the same results, viz., 3 to 3.5.

In the free-settling classifier the following things are essential: (1) means of feeding the pocket with the mixed sand to be treated; (2) rough sorting in the pocket, raising the finished light material by the rising water from the sorting column, and settling the heavy unfinished product to the sorting column; (3) finishing the sorting in the sorting column, allowing the heavy finished grains to settle down and out while the entangled grains are raised to the pocket again; (4) finally, admission of wash water into a pressure box, where the stream is divided, part rising and doing the sorting, the remainder passing out of the spigot with the discharged sand. The third point is most difficult to obtain, as there must be no downward currents to carry slime into the spigot, and the sorting column must have the same rising velocity in all parts of its horizontal cross-section. Classifiers are good or bad according as they do this one thing well or poorly.

What happens in a free-settling classifier is that, with the exception of the first spigot and last overflow, all the products are truly classified, i.e., they contain larger grains of quartz and smaller grains of mineral. The first spigot has an added increment of coarse grains of heavy minerals, and the last overflow has an added increment of fine material in addition to the truly classified grains. Hence, these products require special consideration in concentration.

Hindered Settling.—Under this head the author presents some new figures for the hindered settling ratios as determined in a new series of experiments. The earlier ratio of quartz and galena under hindered settling conditions was 5.85, but in the new series of figures it is 6.92. This figure is true for either continuous or pulsating current, but the latter has an advantage in avoiding the harmful downward currents. Hindered settling thus gives a wider range between the particles of quartz and galena, which are equal settling, than is possible with free settling, the ratios being about 3.5 for free settling and 6.9 for hindered.

The essential feature of getting hindered settling is a hindered settling chamber above with a constriction below, and the whole current of water rising through the two. The cause of the difference between hindered and free settling seems to be that with the latter both quartz and galena are settling in water with a specific gravity of 1, while with the former the grains are settling in a denser medium, probably specific gravity 1.5, due to the crowding of the mineral grains. The effect of hindered settling is twofold: (1) The slime is more per-

fectly kept out of the spigot product and (2) the advanced ratio helps the concentrating machines more than free settling.

The requirement for hindered settling is a proper ratio of area between the settling chamber above and the constriction below. The author has determined this to be 1 to 4, and believes that this will effect a condition of "full teeter" of the bed in the teeter or settling chamber and a discharge through the constriction below.

The author then takes up a consideration of jigs and shows that in the ordinary jig the act of pulsion is identical with that of hindered settling current. The return stroke, or suction, causes an intermission in this action, so that the grains of galena cannot continuously settle through the quartz under hindered settling conditions. In the pulsator jig, however, the conditions of hindered settling are maintained continuously and to this is ascribed the remarkably high capacity of this machine.

Five types of hindered settling classifiers are described. Just as the free settling classifier has an added increment in the first spigot and last overflow, so has the hindered settling classifier, with this distinction: In the latter the larger ratio between the diameters of the grains in juxtaposition is greater, and as a consequence the coarsest product has a larger proportion of all the values in it, and the water in the spigots and overflow are reduced. Fine free mineral grains likely to contaminate the tailings of the succeeding concentrating machines are more easily kept out of those tailings.

Finally, the author takes up various concentrating machines, such as the jig and table, explaining their faults and showing the benefits to be derived from classification or screening.

The original article is long, but will well repay study. Some of the data presented have been published, and numerous references are made to former papers by the author. In addition there is a great deal of hitherto unpublished work, illustrated with numerous cuts.

Ore Sampling.

The Philosophy of Sampling.—The correct sampling of ore is a necessary preliminary to good metallurgical work. In the *Canadian Mining Journal* for Dec. 1, 1910, JOSEPH T. MANDY presents some observations on this subject. Mechanical and hand sampling have had their supporters, and each side undoubtedly has some strong arguments to present, but the weight of argument favors the former method.

The author inclines to the belief that the whole matter of sampling resolves itself into a question of averages, and that in the long run the chance of error favoring either buyer or seller is rather remote. But since the accuracy obtainable varies inversely as the chances for error, he believes that such chances should be eliminated to the utmost. With each chance for error eliminated, the sampling becomes more accurate.

Mechanical Sampling.—The initial feed is of the greatest importance. It should be regular, and hence the author prefers hopper feed to hand-shovel feed. With the latter method the feed is like to be intermittent, and consequently the first cut of the sample may be irregular and incorrect. If hand-feed is adopted it would be necessary to have some intermittent hopper between the crushing apparatus and sampling machine. The same objection to intermittent feed applies to the subsequent treatment of the first cut, for no matter how continuous the original feed may be, it becomes an intermittent one after the first cut unless some device is installed to prevent it. The installation of rolls partly removes this objection, but not wholly, and it becomes apparent that some regulating device should be used after each cut of the sample. Another objection to mechanical sampling is that in the swing of the cutting device coarse particles of ore strike the edges and are likely to be thrown into the wrong compartment. In the ordinary Vezin machine the particles will always be thrown into the reject compartment, but with the Brunton stream diverter it is less likely to occur, while with the Brunton oscillating cutter the possibility of error has an opportunity to average. The greatest point in favor of the mechanical sampler is the elimination of the personal element, which is ever present in hand sampling.

Hand Sampling.—Here the personal equation is the greatest drawback, and no matter how conscientious the operator, his precautions against unfair or incorrect work are insufficient. This becomes true even with unskilled labor, for such operators soon learn the points of the process and eventually work incorrectly. Fractional shoveling, or taking every fifth or tenth shovelful of the ore, is a very poor method save for the poorest ores. Coning and quartering is an operation that is open to the strongest criticism on account of the uneven distribution of the coarse and fine ore in the cone and cake. This method of finally reducing the sample to small size is condemned by the author regardless of whether it is used in connection with preliminary mechanical sampling or hand sampling. A tabulation of figures is given showing the segregation of sizes of ore in a cone and in the resulting cake from which the quarters are rejected or saved.

The author concludes that in all fairness it should be acknowledged that mechanical sampling is superior to hand sampling, but that the latter is open to improvement in the points mentioned. In addition, it is urged that the cutting of the sample should be made mechanical clear through the operation, substituting riffles for the coning and quartering system.

New York Meeting of American Institute of Chemical Engineers.

The third annual meeting of the American Institute of Chemical Engineers was held at New York City from Dec. 7 to 10. The sessions were held alternately at the Hotel Astor, Columbia University and the Chemists' Club. The excursions, a full program of which was given in out last issue, had been carefully arranged so as to be of as manifold and actual interest as possible and were greatly enjoyed; the chain of excursions, distributed over several days, has become one of the most prominent features of the Institute meetings.

Dr. Charles F. McKenna's presidential address dealt in a very interesting way with the Evolution of Portland Cement Processes. We hope to publish the address in full in one of our next issues. An abstract of it and of the other papers presented will be found in the synopsis in this issue.

An especially interesting feature of the proceedings was the discussion on chemical engineering education. Dr. F. W. Frerichs presented the report of the committee on chemical engineering education. Dr. Fred W. Atkinson, president of the Polytechnic Institute of Brooklyn, presented a paper on the development of the chemist as an engineer. Prof. M. C. Whitaker, of Columbia University, presented a paper on the training of chemical engineers which meets the requirements of manufacturers. The general discussion of the subject extended over several sessions. Prof. Whitaker's paper is printed in full elsewhere in this issue.

The election of new officers of the Institute for the coming year gave the following results.

President—Dr. F. W. Frerichs, Herf & Frerichs Chemical Company, St. Louis, Mo.

Vice-Presidents—Mr. George P. Adamson, vice-president and general manager, Baker & Adamson Chemical Company, Easton, Pa.; Dr. Eugene Haanel, director of mines, Ottawa, Ont., Canada; Dr. Leo. H. Baekeland, Yonkers, N. Y.

Secretary—Prof. J. C. Olsen, Polytechnic Institute, Brooklyn, N. Y. Treasurer—Henry S Renaud, New York. Auditor—Herbert Hollick, Camden, N. J.

Dr. Samuel P. Sadtler and Dr. C. F. McKenna are the past presidents. The directors of the Institute are: H. F. Brown, Wilmington, Del.; Ludwig Reuter, Berkeley, Cal.; Thorn Smith, Detroit, Mich.; J. T. Baker, Phillipsburg, N. J.; Dr. W. M. Grosvenor, New York City; Richard K. Meade, Allentown, Pa.; William M. Booth, Syracuse, N. Y.; Dr. Edward G. Acheson, Niagara Falls, N. Y.; Prof. Edward Hart, Easton.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our London Correspondent.)

The Aëration of Portland Cement.

In a paper read before the Institution of Civil Engineers on Nov. 22 Mr. H. K. G. Bamber reviewed past and present methods of manufacture and advocated the abandonment of the practice of "weathering." He said that many engineers—especially those whose experience extends over a long period—have become so accustomed to the use of some aerating process that, perhaps by force of habit, they still continue to require it of their contractors, forgetting that cement which has already passed the stringent tests of the British standard specification has necessarily shown itself to be entirely innocent of any expansive tendencies. If this specification is adhered to for all requirements, the old aeration methods have become as obsolete as the ancient machinery of the cement industry, which has found its way to the scrap-heap. Contrasting the properties of cement made by the old processes with those of the best modern cements, it should not be difficult to convince engineers of the desirability of abandoning an obsolete method of treatment.

Mr. Bamber might have gone a step further and condemned the most undesirable practice of some cement testers in aerating "hot" samples before making the usual physical tests until the rise of temperature has been reduced very considerably. The writer recalls a case which came under his notice rather more than a year ago, in which an analytical chemist who adhered strictly to the British Engineering Standard Specification condemned a sample of cement as thoroughly unsound; another sample from the same source was sent to a certain professional cement tester, who repeatedly reported that the cement was "still too hot to test," and after aërating it for *more than three weeks*, certified that it was sound. The sequel was that the whole of the work executed with that cement had to be taken out and replaced. If a cement contain such quantity of free calcium oxide as will cause an abnormal rise of temperature on ganging, it cannot be satisfactory; and no amount of weathering or aeration will enable such stuff to compare with properly burnt cement free from excess of lime, because the resulting carbonate and hydrate—sometimes referred to as "hydrated carbonate"—must detract from the cohesive power of the cement.

The Detection of Fire-Damp.

At the Society of Arts, last week, Sir H. H. Cunynghame, in a paper on methods of detecting fire-damp in mines, described a simple addition to the ordinary safety lamp by means of which the "cap" which forms over the flame in the presence of methane or other combustible gas is rendered much more conspicuous. With an ordinary flame the cap is usually so pale that it can only be discerned when the lamp is turned down very low, when it was possible to see the cap in the presence of one and-a-half or two per cent of methane, and easy to observe it if the air contained three or four per cent

Professor Cadman and himself devised an improvement which made the cap more visible without unduly diminishing the size of the flame. A small piece of asbestos steeped in sodium carbonate solution and dried was so mounted that it could be brought into the flame of the miner's lamp; and the cap over the resulting bright yellow flame became quite distinct, and rendered the test much more sensitive He had found that sixty hours' continuous burning was required to exhaust the sodium carbonate in the asbestos; and by actual observation in mines had established the fact that one-half per cent of methane could be seen without any difficulty.

Detection of Inflammable Vapor or Gas.

In a paper recently read before the Institution of Engineers and Shipbuilders in Scotland Mr J H Heck described a method of testing air for petroleum vapors and combustible gases. The apparatus consists of a glass syringe, having a capacity of about four fluid ounces, and a small spirit lamp, giving a flame rather more than one inch in height. The syringe is filled with the air to be tested, and the nozzle is brought to a dull red heat in the spirit flame; then, holding the syringe horizontally, with the orifice close to and slightly below the tip of the flame, the air is expelled by a series of slight jerks of the piston.

An inflammable or explosive mixture ignites and burns at each puff with a bluish color for poor mixtures and a yellowish-blue for those richer. Weaker mixtures of air and vapor give a bright incandescent streak or cap; and air free from combustible gas or vapor produces no incandescent streaks, but only a slight flattening or shrinkage of the top of the flame.

This method does not appear to the writer to be wholly free from risk to the operator. Given a mixture having decided explosive properties, the preliminary heating of the nozzle might, in a bright light, be carried too far and cause ignition with possible disastrous results.

Non-Ferrous Electrometallurgy.

Professor Arnold, in his recent presidential address to the Electrometallurgical Society of Sheffield, said that the Sheffield University had arranged to devote £10,000 to the establishment of a department for research in non-ferrous metals. The University was already in a position to investigate the electrical smelting of brasses, bronzes and German silver, having acquired a Kjellin non-ferrous crucible, with which it was also intended to carry out tests to compare the relative efficiencies of electric melting and coke melting of base metal.

The Relation of Chemistry to Metallurgy.

Mr. A. C. Claudet read a paper on this subject at a meeting of the Society of Chemical Industry, held early in November. He said that the development of the composite science of metallurgy might have been much more rapid during the last thirty years—particularly in respect of some of the non-ferrous metals—if metallurgists had kept closer in touch with the advances in industrial chemistry. Both sciences were allied with mechanical engineering; and frequently the greatest difficulties were those encountered in mechanically working out a process.

As demonstrating the relation between chemical industry and metallurgy he instanced the concentration process employed at mines in the South of Spain on cupriferous pyrites; the treatment of Spanish cupreous iron pyrites, imported by England and other European countries, for extraction of sulphur and copper; and the treatment of lead-zinc-silver sulphide ores from Broken Hill. The manufacture of copper sulphate might at first sight seem to be purely a chemical process; but it involved various important metallurgical operations. The Pearce process for auriferous copper was another example.

The arsenical cobalt and nickel silver ores are now worked in Ontario, affording a promising field for chemical and metallurgical research. Their silver content was very large—often thousands of ounces to the ton; but their satisfactory treatment presented great difficulties, for the arsenic sometimes amounted to thirty per cent, and the cobalt and nickel to ten or fifteen per cent each, and a method of recovering all these as well as the silver was wanted.

Market Prices in November.

Copper rose to £57.16.3 on the 2d, remained steady until mid-month, and gradually declined to £57.5.0 on the 30th.

Tin opened at £167.10.0, dropped to £166 on the 9th; then recovered the same figure by the 23d, and rose to £169 at the month's end.

Lead, except for a slight decline on the 9th, kept at about £13.12.6 until the last week, when it declined to £13.11.3.

Hæmatite fell from 65/3 on the 2d to 64/- on the 16th, and improved to 64/6 on the 30th.

Scotch Pig opened at 55/10½, then fluctuated with a minimum of 55/4½, and closed at 55/9.

Cleveland Warrants from 49/10 fell to 49/5½ on the 9th, with but slight improvement until the end of the month, when the quotation was 49/9.

Alum, lamp, loose, per ton	£5.12. 6.
Antimony, black sulphide, powder, per ton	22. 0. 0.
Borax, British refined, crystal, per ton	16. 0. 0.
Sulphate of ammonia, f.o.b. Liverpool, per ton	12.16. 3.
Sal ammoniac, lamp, firsts, delivered U. K., per ton.	42. 0. 0.
Copper sulphate, per ton	19.10. 0.
Caustic soda, ash 48 per cent ordinary per ton	5.10. 0.
Litharge, flake, per ton	15.15. 0
Bleaching powder, 35 per cent, per ton	4. 5. 0.
Sulphur, recovered, per ton	5. 5. 0.
Camphor, 1 oz. tablets	1. 7.
Shellac, standard T. N. Orange spots, per cwt	4. 3. 0.
Hydrochloric acid, per cwt	5. 0.
Copper ore, 10 to 25 per cent, unit	9/4½ to 10.4½.
Tin ore, 70 per cent, per ton	£104 to 106. 0. 0.
Carbolic acid, liquid, 97/99 per cent, per gal	1. 1. 1.
Creosote, ordinary good liquid, per gal	2.
Naphtha, solvent, 90 per cent at 160 deg. C., per gal.	10.
Mica, small slab, original cases, per lb	6d to 1. 0.

India rubber: Paraffine, at the middle of the month prices had fully recovered from the depression at the end of October; and during the last week there has been an advance of 2d. to 3d. per lb.; prices being now steady at 6/3.

Platinum has risen to £8 per oz.

Synopsis of Chemical and Metallurgical Literature

Chemical Engineering.

Evolution of Portland Cement Processes.—In his presidential address to the American Institute of Chemical Engineers Dr. CHAS. F. MCKENNA gave a rapid review of the history of Portland cement from the day of Aspdin's invention, portraying particularly the different stages in the process from the crude method of Aspdin to the modern process of burning in rotary kilns and the fine pulverizing. The economy of the present day is such that for 1 cent 12 lb. of raw material can be taken from the earth, dried, ground, calcined and vitrified and the product ground again. Considerable attention was paid to the old forms of wet processes, and the statement was made that present-day European practice in grinding to semi-wet slurry hard materials, not marls, is the most important advance in modern times and should be taken up more vigorously in America. The basis for this is the claim that the dryer expense is saved, finer incorporation is obtained, better clinkering and easier grinding of the clinker. The critical feature of the modern semi-wet process is to secure the maximum of fineness of slurry with the minimum water. It was said that in good practice some materials can make with less than 35 per cent of water a slurry which can be pumped, and as it dries in the upper end of the long kiln the extra coal consumption is not marked. Modern rotary kiln practice, particularly the long kiln, was touched upon, and the use of preheated air from clinker kilns and diminished indraft of cold air.

Hydrated Lime.—The manufacture of hydrated lime was discussed in a paper of Mr. RICHARD K. MEADE before the American Institute of Chemical Engineers. Hydrated lime is mechanically slaked lime. Just the correct portion of water is added so that the resulting product is a dry fluffy powder. Most of the hydrated limes on the market up to a few years ago were very crude products, usually containing considerable carbonate. Now, however, processes have been perfected which produce a lime consisting almost entirely of the hydrate. The process for the manufacture of hydrated lime usually consists of three stages, (1) crushing the lime, (2) mixing the lime and water, (3) separating the hydrate from the unhydrated portion. In some processes instead of separating the hydrate from the unhydrated portion the two are ground together in some form of pulverizing mill.

The hydrating plant itself is usually located adjacent to the limekilns. The lime is drawn from the kilns and is immediately crushed in some form of rotary or pot crusher. From this it is conveyed mechanically to the hydrator, in which the slaking is done. There are several forms of this latter in use, but all come under two heads, continuous hydrators and batch hydrators. The continuous hydrator most used is the Kritzer hydrator, which consists of a number of cylinders mounted one above the other on a steel framework. Through the middle of each cylinder runs a shaft to which are fastened paddles. The lime is fed in at the upper cylinder and mixed with the water. The paddles stir it up and also force it to travel through the cylinder. It then drops into the next cylinder and here it is mixed up and passed on by the paddles in this and so on until it has passed all of the cylinders. The proportions of lime and water are determined by means of an automatic feed for the lime and a valve for the water.

The Clyde hydrator is a batch hydrator in which the lime and water are weighed in separate charges consisting of about 1500 lb. of lime and the proper amount of water for this much lime. The pan rests upon a ball bearing and is revolved by means of a gear and pinion on the under side of the pan, which is surmounted by a hood and a stack. Plows running across the surface of the pan are fastened to a stationary framework above the latter. The lime and water are fed into the hydrator through an opening in the side, and the plows stir it up and mix the two. When hydration is completed the lime is discharged through an opening in the center of the hydrator, which during the mixing is closed.

After passing through either hydrator that portion of the lime which has been slaked is in the form of a very fine fluffy powder all of which will pass through a very fine sieve. Mixed in with this, however, are always some unslaked lime, unburned limestone and silicious cores. For the better grades of hydrate it is usual to separate out this foreign material by means of screens, although where the amount of these constituents is small they are sometimes ground in with the hydrate. Fuller-Lehigh and Raymond mills are principally used for the grinding, while the separators most used are the Newaygo and the Columbian.

The packing of the hydrate is best done in cloth (100 lb.) or paper (40 lb.) bags automatically by means of the Bates system, which consists of a valve bag and machine for filling the same. The bags are provided with a valve and are tied before being filled. This valve is made by ripping, folding and sewing one corner of the bag. The cement is inserted through the valve by means of a tube on the bagging machine, which automatically fills and weighs the bag. The machinery for hydrating magnesian lime having a capacity of two tons or three tons per hour costs about $5,000 and for high calcium limes $12,000. The cost of hydrating lime is about 25 cents to 30 cents per ton. One ton of lime, however, will often make more than one ton of hydrate.

The advantages of hydrated lime are: It is a fixed product and does not deteriorate with age; it can be handled without risk of fire; it may be shipped by water and packed in cloth or paper bags; it can be used for all purposes for which lime is used and is more convenient than the latter. In addition to this it can be used for mixing with cement, for which purpose quicklime cannot be used.

Bleaching of Oil with Fuller's Earth.—This subject was discussed at considerable length in a paper before the American Institute of Chemical Engineers on Dec. 8 by Mr. DAVID WESSON. The literature of Fuller's earth and its application is very meager. It appears to be first mentioned about 1889. From the best information obtainable Fuller's earth was first used for bleaching fats and oils in Chicago on a large scale

about 1879, or 1880, although it is said to have been used for a long time previous in northern Africa for clarification of olive oil. The first application was very cumbrous, the earth being stirred into the hot oil and allowed to settle, after which the oil was decanted and the residue boiled with water and pressed. The filter press was first used between 1880 and 1882. The efficiency of a given sample of Fuller's earth cannot be readily determined by chemical analysis. The best method is by making a bleach test on a small scale. In comparing the bleaching properties of two earths they should always be passed through sieves of the same size in order to obtain an accurate comparison. Fuller's earth doubtless owes some of its bleaching properties to the presence of a certain amount of water of constitution. This, if driven off by either drying of the earth or by adding it to oil of too high a temperature, will prevent bleaching. The reason why Fuller's earth seems to bleach is not positively known. Fuller's earths differ greatly in their absorptive properties and show great differences in their liability to spontaneous combustion. The arranging of filter plants is a matter of considerable importance. The best place for filters is on the top of a refinery under suitable shelter. By having them at an elevation above the bleach tanks oil can be allowed to run back to the same, or can be fed to any part of the building, or run easily to storage by gravity; besides, the fire risk is much less, and when the filters are steamed out the nuisance of the steaming is entirely done away with. The mixing kettles for oil and Fuller's earth are practically cylinders provided with mechanical agitation and suitable heating coils. Filter pumps should be slow moving, capable of working up to a pressure of 150 lb. to 200 lb. The operation of the filter plant is quite simple. The earth is mixed with the oil at the proper temperature and then pumped through the filter press, the first portions of the oil being allowed to run back to the mixing kettle, or bleacher, as it is often called, until it comes up to the required standard, after which it runs directly to storage.

Fitzgibbon Boiler.—In a paper read before the American Institute of Chemical Engineers Mr. Jerome Alexander gave a brief description of the construction and operating principles of the Fitzgibbon boiler, a type combining vertical with horizontal tubular features. The boiler is internally fired, and is entirely without external or internal brickwork, thus avoiding the annoyance and expense of repairs at inopportune times. A heavy asbestos or magnesia covering reduces radiation below that found in ordinary bricked-in boilers. The boiler is a quick steamer, economical in coal consumption, and can be easily moved about.

Sewage Disposal.

The problem of sewage disposal was the subject of a symposium of papers presented at a joint meeting of the New York Section of the American Chemical Society and of the American Institute of Chemical Engineers at the Chemists' Club in New York City on Dec. 9.

Basic Principles.—Mr. Geo. C. Whipple pointed out in his paper that the basic principles underlying all methods of sewage disposal are to get rid of sewage without danger to the public health, with the least possible nuisance to the smallest number of people, with the least damage to property, and at the smallest cost. The process of purification is usually carried on in several stages: First, a partial removal of the suspended matter by screening or sedimentation, or both; second, a process of oxidation using sprinkling filters, contact beds or sand filtration, and, third, a final removal of bacteria by sand filtration or disinfection. The term "sewage purification" is popularly applied to any or all of these processes. This has contributed not a little to confusion of ideas. Laymen innocently suppose that when sewage is "purified" it becomes pure, whereas the sanitary engineer may mean only that it is purer than it was before. How much purer depends upon the method used. It would be of decided benefit to the question of sanitation if more definite terms were used, such as sewage clarification, oxidation, deodorization, disinfection, filtration, etc.

The chief danger from sewage is the contamination of public water supplies. For the protection of public water supplies it is not safe to depend upon sewage purification works alone unless more than ordinary precautions are taken, for the reason that most of the processes cannot be depended upon to remove bacteria from the sewage to a sufficient extent, while with the combined system in use complete purification is impossible. Sewage purification is of advantage, as it offers a second line of defense, an increased factor of safety. It also serves to prevent nuisances to sight and smell, which are of real damage to property and affect personal comfort. Sewage works themselves, however, may be the cause of similar nuisance.

What appears to be needed in this country at the present time is some method of co-operation by which needed sanitary reforms can be brought about at least expense. It is unbusinesslike to compel the purification of the sewage of a large upstream city in order to protect the water supply of a small city lower down, provided pure water can be furnished the latter in some better and cheaper way. Legislation that clothes the State authorities with power to prevent the pollution of sewage, but does not give them power to compel the purification of water or to control pollution by trade wastes, is unfortunate. It naturally leads to litigation rather than co-operation and may retard rather than hasten necessary sanitary reforms. If our State authorities cannot be trusted in this matter it may be that a proper solution of the difficulty will be found in the establishment of district boards similar to those in England and Germany, such boards having jurisdiction over the limits of particular watersheds. In some respects these natural hydrographic boundaries have advantages over artificial State boundaries. In the near future also our national government will take a hand in the matter. In whatever form the authority may be constituted the idea of co-operation should prevail, and ironclad rules against stream pollution should give way to a rational distribution of the burden of purification of both water and sewage, and an equitable adjustment of cost made between the parties interested, thus decreasing the total expense of sanitary measures required and utilizing natural resources for the purification of sewage in water as far as this is safe.

If the system of water carriage of sewage continues in use the time will some day come when the sewage of all of our cities will be purified, partially or completely, and all surface water supplies filtered. It is proper to anticipate this consummation as far as our means permit, but meantime it is good business and sound common sense to spend our money first where it will go furthest and do the most good, building water filters and sewage purification works, sometimes one, sometimes both, as they may be needed. Adequate remedies against stream pollution from the standpoint of nuisance have been usually obtained by an appeal to the principles of common law. Cases involving bacterial pollution by sewage have been thus far too few to establish definite precedents. It will be interesting to see whether, in view of our increasing population, and especially the increasing growth of our cities, the courts will ultimately decide that the use of unfiltered river water as a source of water supply by riparian owners is a reasonable use of the water. The speaker was optimistic in regard to the improvements that are being made in methods of sewage disposal. He believes that the near future is to see extensive developments in the art. Important as are the recent improvements in the technical details, still more important and necessary is a rational assignment of the means employed to the work at hand. The use that is to be made of the water into which sewage is discharged and the conditions tending to natural purification are to be studied with greater minuteness than ever before; the method of dilution is to be used more

rationally, and the designs of the sewage disposal plants made to fit more closely the particular conditions. The general result will be the construction of more and simpler plants for the treatment of sewage and, where occasion makes necessary, the installation of yet more efficient devices for bacterial purification than those now employed.

Sewage Disposal in Europe.—Dr. RUDOLPH HERING gave in his paper a review of European practice. Disposal of sewage by dilution was first practised. Of the 16 largest cities in the world having a population of over 1,000,000 inhabitants every one without exception now employs the dilution method where flowing water is available and a sufficient quantity of oxygen is dissolved in it to represent a flow of fresh water equivalent to at least 3 cu. ft. per second for every 1000 persons discharging sewage. Where a water supply is taken from a river it must be purified even after any sewage entering above has been treated. Where a river is not used as a water supply sewage may contaminate the food fish, oysters, etc. The commercial value of such food is insignificant compared with the cost of removing all the conditions that would impair their hygienic qualities. It is therefore much cheaper to take them at a greater distance from the large cities where no dangers exist.

The nuisance to sight produced by sewage is almost everywhere in Europe prevented by keeping all plainly visible floating matter out of a river by screening. Screens with a mesh as small as 1 mm are used. The nuisance to smell is prevented by constructing sewers with such smooth interior surface and good grade as will deliver the sewage practically fresh to the outfall and insure an immediate submergence of the sewage as far below the surface of the water as possible. This method is entirely successful in many Continental cities. The amount of sewage discharged into the Thames is so regulated that the dissolved oxygen in the water does not generally fall below 30 per cent of saturation. No nuisance results under these conditions. European experience justifies the conclusion that purification of sewage by the oxygen in flowing water is entirely satisfactory.

Sand purification of sewage requires the delivery of the sewage in fresh condition and a preliminary separation of the coarser suspended particles, after which the finely divided matter may be oxidized in intermittent sand filters. The more recent developments involve improvements on the septic tank method of purification. Dr. Imhoff has developed a tank having two compartments. In the upper the suspended matter settles out and is drawn off through a slot. In the lower compartment the sewage is decomposed with the evolution of methane, carbon monoxide, and dioxide. No sulphuretted hydrogen is produced. The decomposition is complete in from three to six months. The sludge which is removed dries quickly to a friable material similar to garden mold. The annoying question of the disposal of sewage sludge may therefore be considered satisfactorily settled.

Sewage Disposal in New York.—This was discussed in a paper by Dr. GEO. A. SOPER. For the most part the sewage of New York is conveyed in crude condition by the shortest route to tide water and discharged at or near the surface of the water. There are over 500 sewer outlets discharging 600,000,000 gal. of sewage per day. In all parts of the harbor above the Narrows the water is seriously polluted and rendered objectionable both to sight and smell. Along 175 miles of shore the water is so polluted as to be dangerous to bathe in. These conditions will rapidly become worse as the population increases. A standard of purity for the water of New York harbor has been proposed by Colonel Black and Professor Phelps as a result of studies, estimate and apportionment. They consider that the dissolved oxygen in the water should not fall below 70 per cent of what would be present if the water did not receive any sewage. This limit has already been exceeded. A definite plan and program of main drainage, including outfall works and purification plants designed to improve the present unsanitary conditions, have been proposed by the Metropolitan Sewage Commission. The duty of carrying out this plan so far as New York is concerned has been intrusted to this commission. This work is now progressing satisfactorily.

Unsolved Problems.—Prof. C. E. A. WINSLOW discussed in his paper unsolved problems of sewage disposal. The three main ends of sewage treatment—the elimination of suspended solids, the oxidation of organic matter, and the destruction of pathogenic bacteria—can all be attained by practically efficient methods, but there are minor difficulties to be overcome in each case. The pathogenic bacteria can be destroyed when necessary by disinfection with bleaching powder, but the dosing devices available for use in small plants are very defective. The oxidation of organic matter can be economically effected by the use of sand, contact or trickling beds. Distribution systems for trickling filters require further study. The intermittent sand filter has possibilities of intensive action not attained in plants operated at present largely at haphazard. It is the accumulation of suspended solids on the surface which keeps the capacity of sand beds down to 100,000 gal. per acre per day and experiments carried out at the Sewage Experiment Station of the Massachusetts Institute of Technology show that the rate can be raised to 200,000 gal. or 300,000 gal. if suspended solids are removed by careful preliminary treatment. Sludge disposal is still the most serious of the unsolved problems of sewage treatment. It has been minimized at the Technology Experiment Station by the use of a deep tank on the septic principle, but so operated that the sewage rises and washes the sludge continually, and thus keeps it from becoming overseptic. By this means the liquefying process is so accelerated that over 70 per cent of the deposited total suspended solids have been liquefied. The utilization of sewage sludge, though not yet economically realized, furnishes promising possibilities to the industrial chemist in the future.

Mr. NICHOLAS S. HILL, JR., presented a paper on sanitary conditions in their relation to water supplies in the vicinity of New York City, touching upon the principal legal questions involved in the problem.

Recent Metallurgical and Chemical Patents

Gold and Silver.

Clancy Cyanide Process.—The details of the improvements which have been made in the cyanide process by JOHN COLLINS CLANCY were given in our issue for November, 1910, page 623. They are again mentioned here in order that those desiring to secure copies of the United States patents may do so. (976,043-4-5, Nov. 15, 1910.)

Zinc.

Production of Zinc Powder.—In the process of first making zinc oxide and then reducing the oxide in a separate process, OLIVER B. DAWSON, of El Paso, Tex., proposes to introduce into the zinc vapor, at a point just above or close to the bed of the mixture under treatment, sprays of water gas. The object of this is to supply carbon monoxide to combine with oxygen present, either free or combined with zinc, forming carbon dioxide, and leaving metallic zinc in the form of fume which is subsequently condensed. (976,557, Nov. 22, 1910.)

Rare Metals.

Pyrophoric Mass.—An improved invention relating to those substances which give off sparks of great intensity when rubbed with a metallic substance has been patented by DR. CARL AUER VON WELSBACH, of Vienna. These substances are of value in igniting liquids, solid and gaseous bodies, as well as for the purposes of illumination, signaling and photography. The inventor has discovered that cerium, or metals of the cerium group, may be treated to form a pyrophoric body which is hard and durable, resisting the decomposing action of air.

Since the pyrophoric property of the metal seems to lie in its suboxides or nitrides, the procedure is as follows: The metal is first reduced to fine powder, then compressed into suitable molds by a pressure of from 1000 kilos to 25,000 kilos per square centimeter. This mass is slightly pyrophoric, but the property is further increased by heating with an equal volume of air in a metal casing having thin walls. The temperature is raised gradually to incipient red heat, when a lively reaction ensues and the mass frits together. The fritted mass is stable and is so highly pyrophoric that when a knife-blade is drawn across it an actual sheet of flame is produced. For varying the hardness of the alloy certain other metals such as zinc, tin, lead, calcium, magnesium and aluminium may be added. (976,760, Nov. 22, 1910.)

Melting Furnaces.

Crucible Furnace Cover.—Furnaces adapted to the melting of metals in crucibles are not always provided with covers which prevent the flame of the furnace coming in contact with the metal, thereby oxidizing it and causing loss. It is the object of a recent invention by Julian L. R. Brown, of Bridgeport, Conn., to provide a cover for a furnace, which shall at the same time act as a cover for the crucible and prevent the deterioration of the metal by the action of the flame. The device will be understood by reference to Fig. 1, which shows a plan of the cover and a section of the furnace. The cover may be made of any suitable material, such as fire-clay, graphite or brick. The essential features are the central portion adapted to cover the crucible, and escape holes for the flame, in alignment with the flame gap surrounding the crucible. Various modifications of the idea are also patented. (975,506, Nov. 15, 1910.)

Charging Melting Furnaces.—In practice there is considerable wear on melting furnaces, and especially on electric furnaces, by throwing in the rough scrap and metal, which digs into the sides of the furnaces and weakens them. To obviate this difficulty Michael R. Conley, of New York has patented a cartridge of sheet metal adapted to fit the melting pot of the furnace and contain the charge to be melted. The entire surface of the cartridge comes in contact with the

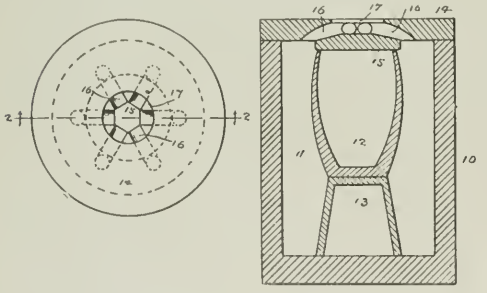

FIG. 1.—CRUCIBLE FURNACE WITH COVER

hot furnace wall and the charge begins to melt evenly and quickly. In practice the cartridge may be made of any desired composition, and thus not disturb the nature of the melted product. (975,751, Nov. 15, 1910.)

Reversible Heating Furnaces.

Furnace Head for Gas Furnace.—Relating to furnaces in which gas and air are simultaneously introduced and in which the stream of gas and air is periodically reversed, Bruno Versen, of Dortmund, Germany, has patented an improved furnace head, illustrated in Fig. 2. An object of the invention is to improve the caloric efficiency of the furnace by providing apertures in the furnace head for the escape of the "heat," i. e., the combustion mixture of air and gas, said apertures being at about the same height as the apertures for the introduction of the gas. By this means the air which served for raising the temperature of the heating flame is maintained within the said flame in the entire interior space of the furnace.

In the improved head air is conveyed by vertical lateral flues L which open into the top of the furnace by a common port L'. Gas is allowed to enter by a flue between the air flue and by a port below the common air port. Below the latter branch flues Z extend from the lateral flues L and open into the furnace as the gas flue G. When the head is acting as an exhaust, the heat on the hearth of the furnace will be conveyed through Z. When the head serves as an intake the blast of

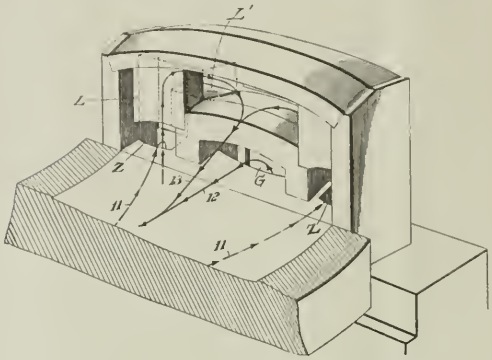

FIG. 2.—FURNACE HEAD FOR GAS FURNACE.

air will come in through L, and owing to its momentum will pass Z and enter through L'. For the purpose of protecting the furnace head against undue deterioration the inventor places cooling pipes in various portions of the head, not shown in this illustration. The system of piping also serves as a reinforcement, resisting vibrations and jars. On account of the advantageous distribution of the air the weight of the head may be decreased, so that even in very large furnaces the head may be easily removed. (975,738, Nov. 15, 1910.)

Roasting Furnaces.

Roasting Sulphides or Sulphates.—In a furnace of the superposed hearth type, Utley Wedge, of Ardmore, Pa., has introduced a modification designed to facilitate the elimination of sulphur from ore, particularly in the latter part of the roast. In the drawing, Fig. 3, is shown a furnace of the type mentioned, with the addition under consideration. The furnace is divided into two sections, upper and lower. In the upper section the roasting operation proceeds as usual, but on coming to the lower section the ore is fed through a seal formed by a shelf below the passage from upper to lower sections. The ore is scraped from the shelf by an arm attached to the upper rabble of the lower section. Between the arch of the upper chamber of the lower section and the hearth of the lower chamber of the upper section is provided means for introducing a carbonaceous reducing agent such as coke breeze or pulverized coal. This will reduce any sulphate compounds which may have been formed and will permit the elimination of the remaining sulphur by the application of a temperature approximating 1200° F., as compared with 1600° F. or 1800° F. commonly required in the lower portion of the furnace as usually operated. Arrangement is made to permit of either mixing the gases from both sections, or conveying them from the furnace separately. By preference the lower section of the furnace is of the muffle type, the heating chambers being supplied with the products of combustion from a heating furnace shown at the side. (976,525, Nov. 22, 1910.)

Roasting Furnace.—An improvement in his well-known roasting furnace has been patented by John B. F. Herreshoff, of New York. The object is to improve the life and efficiency

of the apparatus by proper cooling arrangement. The hollow shaft of the furnace is closed at its upper end and has a surrounding sleeve and rabbles attached to the shaft. Connection is made between the rabbles and the shaft and sleeve, whereby air may travel upward through the shaft, thence outward into each rabble arm and back into the sleeve, which is open at the top. By this circulation of air, which is driven by a blower, the hot parts of the furnace are cooled. (976,175, Nov. 22, 1910.)

Annular Roasting Kiln.—A furnace of this type with a number of novel improvements has been patented by JOHN

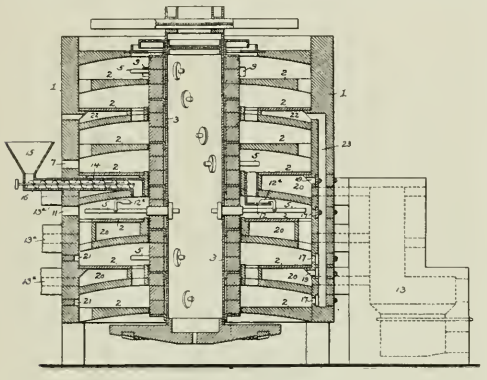

FIG. 3.—ROASTING FURNACE.

ZELLWEGER, of St. Louis, Mo. The principal features are means for recuperating heat from the fire gases; the use of warm air for oxidizing the charge; separation of sulphur gases from the products of combustion; and variation of temperature in the several zones of the hearth, whereby the ore may be locally heated to different degrees of temperature. (976,769. Nov. 22, 1910.)

On account of limitations of space a very large portion of Synopsis and Patent Abstracts had to be reserved for our February issue.

Vacuum Evaporator.

Evaporators are employed in many industries, often in the recovery of valuable constituents of solutions ordinarily considered worthless; frequently, too, unutilized exhaust steam occurs. In such cases a multiple-effect evaporator operated by this exhaust can be utilized to the greatest advantage. As an instance, it is only within the past few years that the tank-water which occurs in packing houses, etc., has been evaporated and its valuable solids recovered.

This tank-water averages from 5 per cent to 7 per cent solids; the smallest packing and rendering plants produce several hundred gallons daily and the value of the solids contained averages $35 per ton, whereas the cost of producing them, by means of the multiple-effect evaporator, will not exceed $10 per ton. An evaporator should, therefore, pay for itself in from six to eight months, depending upon the quantity and quality of the water.

The following notes refer to the construction and uses of the Redfield "standard evaporator," built by Messrs. Robert S. Redfield & Company, 90 West Street, New York City, for the evaporation of tank-water, glue, gelatine, garbage liquors, spent lyes, caustic potash, beef extract, cane and beet sugar, glucose, tanning extract, brine copperas, and many other special liquors occurring in chemical works and other establishments.

The Redfield standard evaporators are of the vertical tube type with circular steel shells or square cast-iron shells, both types being fitted with removable heat chambers, built with copper, steel or charcoal-iron tubes, as necessity requires. The entire heating chamber is removable en bloc from the body of the evaporator.

The shells are fitted with manhole and side glass fixtures, affording at all times an easy access to and a clear view of the interior of the shells.

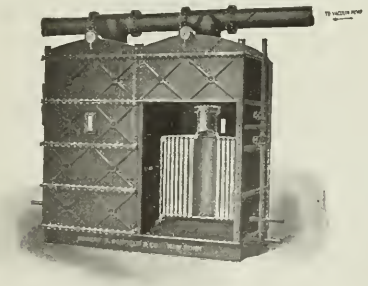
The fundamental distinction between the Redfield standard and other types of evaporator lies in the fact that in the Redfield apparatus the steam is outside instead of inside the tubes. The liquor therefore is afforded a free circulation upward through the tubes and returns to their base by way of the open space between the shell and the steam drum proper.

When the steam is caused to enter the steam chamber the heated liquors at once rise in the vertical tubes. There is nothing to impede this movement and with increasing temperature and higher vacuum the movement of the liquor becomes so rapid that jets will be thrown up often to a height of 2 ft. or 3 ft. It is obvious that this hot liquor must in some manner return to the base of the evaporator, which is cooler than the tube passages from which it emerged. This passage is provided by the space between the steam drum and shell, with the result that there is a constant and exceedingly rapid and automatic circulation of the water rising through the tubes, thence around the heating chamber to the base of the tubes.

By virtue of this vertical-tube construction the tubes automatically clean themselves due to the extremely rapid passage of the liquor throughout their length while the high speed at which the liquor circulates entirely prevents incrustation, resulting in freedom from tube repairs and saving in steam.

In the latest type of the Redfield standard evaporator the steam in each effect enters the center of the steam chamber. This construction at once insures a perfectly even steam distribution, which in part accounts for the remarkable reserve capacity. The condensation being automatically and immediately removed the full efficiency of the steam is constant. For this reason this type of evaporator is particularly well adapted for such liquors (like glue and gelatine) where quick evaporation is required, as too long contact with hot surfaces would deteriorate the quality of the product.

The tubes in the steam chamber are expanded into the tube



EVAPORATOR.

sheets by the same method that boiler tubes are expanded into the tube sheets of high-class boilers.

If steel tubes are employed they have a practically unlimited life. Copper tubes, owing to the great expense, are never used heavier than 16-gage, and these light tubes cannot be kept tight for any great period of time nor can they stand up as would a heavier tube. Practically the only other maintenance expense is on the pumps.

The fact that the steam chambers in the Redfield standard evaporators are entirely separate from the main body permits the removal of the entire steam chambers and the replacement of steam chambers with from 50 per cent to 100 per cent increased capacity.

These evaporators are virtually automatic in operation. The feed valves may be so regulated that a constant supply of fresh tank water is drawn in to counterbalance the rapid evaporation. Each plant is provided with a stick testing funnel so constructed that a quantity of the concentrated liquor may be withdrawn from the last effect quickly and easily to be tested for density. Opening a valve at the base of this funnel allows the vacuum to pull the tested liquor back into the evaporator. This method prevents all loss of concentrated liquor and is extremely simple.

An entire evaporating plant, either single or multiple effect,

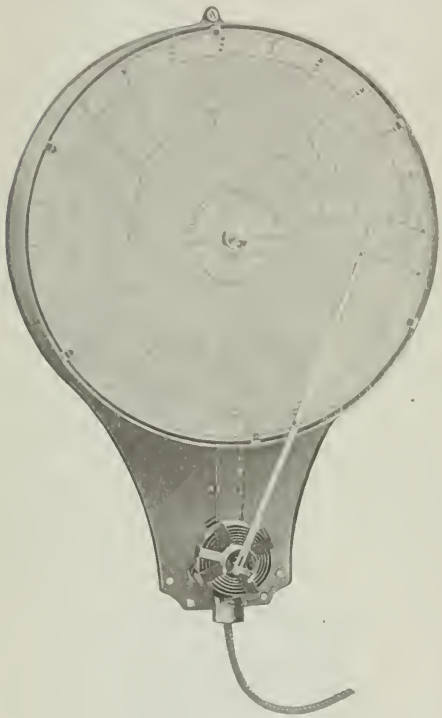


FIG. 1.—INTERIOR CONSTRUCTION OF RECORDING THERMOMETER.

may be easily handled by ordinary labor. In plants up to 2000 gal. only a part of one man's time is required.

To save floor space in multiple-effect evaporators all space may be eliminated between different effects The length of the large vapor piping as well as all other piping connected with a multiple-effect plant of this type is reduced to a minimum.

A double-effect Redfield standard evaporator is shown in the adjoining diagram. Messrs. Robert S. Redfield & Company build their standard evaporators in any capacity from 100 gal. to 5000 gal. per hour.

High-Pressure Tanks.—For containing gases or liquids under pressure cylinders that are merely riveted and calked have often proved unsatisfactory; such a cylinder may even be perfectly tight under a high-pressure water or liquid test, yet may be found to leak badly when only a slight air or gas pressure is applied. For this reason brazed tanks or cylinders are now generally preferred for high-pressure tanks. With a brazed tank it is well known that the brazed joints or seams are the strongest parts, as they form a perfect union when properly brazed. Concerning such brazed high-pressure tanks interesting information may be found in the catalog of the manufacturers, the Wm. B. Scaife & Sons Co., of Pittsburgh.

Compensated Gas-Filled Recording Thermometers

During the last 15 years recording thermometers of the Bristol Company, of Waterbury, Conn., have been constructed in various different forms, depending for their operation on the expansion of a liquid, the expansion of the vapor of a liquid, or the expansion of a gas. These thermometers have been used very extensively for ranges of temperature up to 800° Fahr., but the models equipped with flexible connecting tubes between the sensitive bulb and recording instrument and depending for their operation on the expansion of a vapor or a gas have not until recently been adapted for recording the lower ranges of temperature.

A new compensated gas-filled Bristol recording thermometer has recently been developed for recording the lower ranges of temperatures, such as atmospheric temperatures, temperatures of water, temperatures of brine in refrigeration systems, etc., and found satisfactory in numerous tests. These thermometers are equipped with a patented compensating device which automatically corrects for changes of temperature at the recording instrument.

Bristol's gas-filled class III recording thermometers are equipped with sensitive bulb and flexible capillary connecting tube and a pressure tube, as shown in Fig. 1, the sensitive bulb and flexible connecting tube and spiral pressure tube all being filled with an inert gas under pressure. Changes of temperature at the sensitive bulb cause corresponding changes in the pressure of the confined gas and these changes in pressure are measured and recorded by the recording instrument. The sensitive bulb is usually about 10 in. long and ¾ in. in diameter and the volume of gas contained in this sensitive bulb is very large in proportion to the volume of gas contained in the fine capillary connecting tube between the sensitive bulb and the recording instrument, this making the error due to changes of temperature along the connecting tube negligible.

Scientists have long recognized the fact that an air or gas

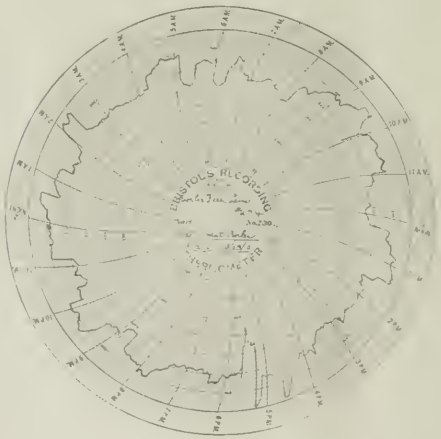

FIG. 2.—RECORD OF FEED WATER TEMPERATURE.

thermometer is the ideal type of apparatus for measuring low temperatures, provided that the air thermometer can be manipulated in the laboratory, where it is possible to make various corrections. The very important new feature of the Bristol compensated gas-filled recording thermometer is the patented compensating attachment for the spiral pressure tube, shown in Fig. 1, since a thermometer equipped with this compensator gives the same readings or record when the temperature at the recording instrument changes as it would if the temperature at the recording instrument remained constant.

The need for such a compensator can be illustrated by the

application of a recording thermometer for recording temperature of brine in a refrigeration system. The temperature of the atmosphere at the point where the recording instrument was installed might change, although the temperature of the brine at the point where the sensitive bulb was installed remained constant and a recording thermometer for brine temperature should, of course, be so constructed that it would be affected only by changes of temperature at the sensitive bulb.

Fig. 2 shows a record of feed water temperature as recorded by one of these instruments, the chart having range of 40° Fahr. to 225° Fahr. It will be noted that the scale of this chart has uniform graduations over the entire range and this makes it possible to use the Bristol-Durand radii averaging instrument for computing the average of the feed water temperature for the 24 hours.

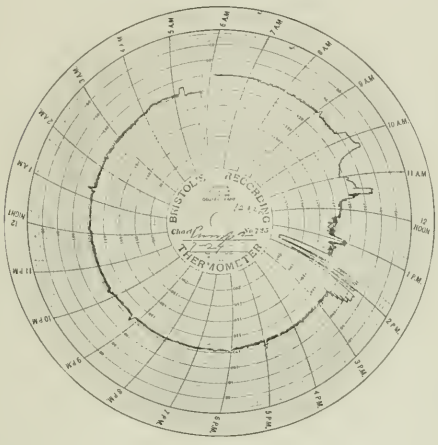

FIG. 3.—RECORD OF CONDENSER WATER TEMPERATURES.

Fig. 3 shows a record of condenser water temperatures, as recorded by one of these thermometers on a chart having range of 40° Fahr. to 220° Fahr. It will be noted that this chart has a reversed scale of uniform graduations. For condenser water temperatures the reversed scale is a desirable feature, as the average temperatures are usually lower than 125° Fahr., whereas the temperatures are likely to reach boiling point occasionally, at times of loss of vacuum in the condenser, as shown by the record in Fig. 3, between 1:30 p. m. and 1:45 p. m.

American Museum of Safety.—The formal exercises in connection with the permanent exhibition of safety devices of the American Museum of Safety were held on Nov. 21 at the Auditorium of the Engineering Societies Building, 29 West Thirty-ninth Street, New York. The object of the Museum is the conservation of human life by means of a permanent exhibit of the best and most practical safety devices for making safe the dangerous parts of machines and processes. Mr Philip P. Dodge presided. Among the speakers were the director of the Museum, Dr. W. H. Tolman, who discussed Germany's system of accident prevention; Prof. F. R. Hutton, Mr. T. C. Martin, Mr. E. S. Lott and Dr. N. E. Ditman. Mr. S. C. Dunham, president of the Travelers' Insurance Company, presented the gold medal offered by his company to the individual industrialist or corporation that has done the most for the protection of the lives and limbs of their workmen by means of safety devices for machines or processes to the United States Steel Corporation Mr. W. B. Dickson, first vice-president, accepted the medal on behalf of the Steel Corporation.

Personal

Dr. **Leo H. Baekeland,** of Yonkers, N. Y., has been awarded by the City of Philadelphia, on the recommendation of the Franklin Institute, the John Scott Legacy Premium and Medal for his invention of bakelite, in accordance with the report of the Institution's committee on science and arts, adopted May 4, 1910.

Mr. **Walter Brinton,** superintendent of the manganese steel department of the Taylor Iron & Steel Company's plant at High Bridge, N. J., since 1895, has resigned and has accepted a position as consulting engineer for the Edgar Allen American Manganese Steel Company, which is manufacturing manganese steel at Chicago Heights, Ill., and at New Castle, Del. Mr. Brinton's headquarters will be at the New Castle plant.

Dr. **Allerton S. Cushman** has resigned his position with the United States Department of Agriculture to found the Institute of Industrial Research in the City of Washington. The object of the Institute will be to undertake investigations of industrial problems in all lines, but more particularly of investigations concerning the protection and conservation of industrial metals; agricultural, land and fertilizer problems; hydraulic cements; paint technology; chemical industry, chemical engineering and electrochemistry. The Institute will be located in the heart of the City of Washington, near the White House, and fronting upon the Potomac River Park. Dr. Cushman has associated with himself Mr. Henry A. Gardner, who will have charge of the division of paint technology, and Dr. N. Monroe Hopkins, who will be in charge of the division of electrical engineering and electrochemistry.

Mr. **I. A. Goodell,** well known among smelting men in the West, was in Denver last month, having completed the work on which he was engaged in Montana.

Mr. **H. A. Guess,** manager of the Federal Lead Company, Flat River, Mo., recently spent some time in Salt Lake City on professional business for the interests with which he is connected.

Mr. **George A. Guess** is now metallurgical superintendent for the Cerro de Pasco Mining Company, Cerro de Pasco, Peru.

Dr. **Leo F. Guttmann** and Mr. **Camillo J. Guttmann** announce that the practice of their father, the late Mr. Oscar Guttmann, is now being carried on by them under the name of Oscar Guttmann & Sons. Specialties of their consulting practice are the erection of explosive plants, acetone, sulphuric acid, nitric acid and acetic acid plants, the fixation of atmospheric nitrogen as nitric acid, nitrates and cyanamides, the design, erection, remodeling and supervision of chemical factories, etc.

Mr. **D. C. Jackling,** of Salt Lake City, who is in charge of the operations of several of the large Western copper propositions, has found it necessary to deny a persistent rumor to the effect that he would assume general managership of all of the Guggenheim Western interests.

Mr. **Robert Kann** has formed partnership with Mr. R. J. Wysor in order to extend the scope of his laboratory. Mr. Wysor has been connected for a number of years with the Carnegie Steel Company. The new firm is established at 62-64 Gold Street, New York City, and is prepared to do general metallurgical work and to take charge of weighing and sampling of shipments.

Senor **Ramon F. Lujan,** of Mexico, has been spending some time in Denver on business relating to zinc production in Mexico.

Mr. **Charles Mindeleff,** chief chemist for the A. S. & R. Company, Perth Amboy, N. J., has been making a tour of the Western United States Mints in a professional capacity.

The Colorado School of Mines has issued a biennial report on the condition of the institution. In the last report, 1908, the enrollment was 307 students, of whom 46 per cent were from outside the State. At present the enrollment is 331 students, of whom 53 per cent are registered from outside the State. Six years ago only 26 per cent of the students were from outside the State. Thirty-six States, the District of Columbia, Alaska and the Philippine Islands are represented in the student body, in addition to seven foreign countries. The total number of graduates, including 1909, is 580. The inventory of property shows a total value of $723,841, a gain of 11.6 per cent in the biennial period. The report contains an appendix on non-metallic minerals of Colorado, by J. C. Bailar.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Electric Furnaces (Continued).

695,939, March 25, 1902, Clarence S. Loman, of Everett, Mass.

Resistance type, for the production of oxides of tin and lead. The furnace is a horizontal trough having its ends widened and deepened to receive vertical terminal plates of copper. The narrow intermediate portion of the trough is covered by a collecting chamber, through one side of which project tuyères. A flue or chamber for the oxidized products opens from its other side. For the manufacture of binoxide of tin the metal is preferably maintained at a temperature of about 1200° C. and air is suplied at a temperature of about 400° C. To produce putty powder—a mixture of the binoxide and protoxide of tin—the molten tin is maintained at about 1200° C., and cold air is introduced. Cold air is also used for the manufacture of lead oxides.

696,004, March 25, 1902, George D. Burton, of Boston, Mass.

Arc-in-liquid type, for the smelting of ores of gold, silver, lead, etc. The charge is distributed in receptacles molded from fireclay and railroad cinders and baked. These receptacles have perforated flat bottoms dipping into a solution contained in a tank. The level of the solution is varied by a displacing plunger. The positive electrode is a vertical lead plate in one end of the tank. Each receptacle contains a negative electrode, imbedded in the charge, being a disk of carbon on one of copper, carried by a swinging arm. The receptacles are covered. In operation an arc is established between the liquid and the charge in the receptacles. The molten products pass through the perforated bottoms and are chilled in the liquid. The volatile products escape through a pipe leading from the cover to a condenser. Baffles in the pipe retain solid products. For the treatment of ores containing nickel, iron, sulphur and arsenic the solution may consist of water, 30 gal.; salsoda, 10 lb.; and sodium chloride, 2 lb. For the treatment of lead or silver-galena ores the solution consists of water, 30 gal.; and sodium chloride, 10 lb. For the treatment of silver-galena ores an electrode disk of antimony may be substituted for that of carbon. Ores containing sulphur, antimony and arsenic are fluxed with chlorides of sodium and ammonium. It is stated that ores containing gold, silver and lead give separate globules of these three metals. Oxygen may be injected into the escaping sulphurous fumes.

697,810, April 15, 1902, Michael R. Conley, of New York.

Resistance type, for the reduction of iron ores and production of steel for ingots. The furnace is a vertical stack, having a constricted portion toward its bottom. Radial electrodes of mixed plumbago and clay project through the walls at its neck. Other radial electrodes pass through the walls of the crucible beneath, which has tap holes for metal and slag. The metal decarburized at the neck can be recarburized or treated with manganese in the bath below.

698,766, April 29, 1902, A. Voelker, of Ehrenfeld, Germany.

Combined arc and resistance type. Materials for making glass are forced upward through conduits, by screw-conveyors, into electric arcs. The fused product runs downward into a refining pot, wherein it is heated by a current passed directly through it, between carbon-plate electrodes situated behind perforated partitions. The current density is 5 amp per square millimeter of electrode surface. The refined product overflows into a third chamber beneath. The walls of the melting and refining chambers are of chamotte.

BOOK REVIEWS.

More Recent Cyanide Practice. Edited by **H. Foster Bain.** Second edition. 418 pages, 88 illus. Price, $2. San Francisco: Mining and Scientific Press.

This is an appendix to (not a second edition of) "Recent Cyanide Practice," and is a reprint of articles on this process which have appeared in the *Mining and Scientific Press* from 1907 to 1910. In the 77 articles here reprinted is to be found some of the most recent information on all phases of the process. While too much in detail for general reading or students' use, yet the collection will be of great value to every practical user of the cyanide process.

Van Nostrand's Chemical Annual. A handbook of useful data for analytical, manufacturing, and investigating chemists and chemical students. Edited by **John C. Olsen,** A.M., Ph.D., professor of Polytechnic Institute, Brooklyn. Second issue, 1909. 580 pages. Price, $2.50 net. New York: D. Van Nostrand Company.

The first edition of this "annual" appeared in 1907, the second around January, 1909. Thus the term "annual" is misleading. However, there is really no inherent reason why a book of this kind should be republished every year. In spite of the rapid advance of chemistry in many fields a very large part of the book must always remain unchanged in succeeding editions; and many of the minor changes, especially those caused by the yearly changes in the "international" atomic weights, would be too insignificant to induce American chemists to buy a new edition every year.

The book is decidedly useful and has deserved the favorable reception which has been accorded to the first edition. It is what it is intended to be, a convenient reference book of numerical data, and it is especially to be recommended that all tables and numerical data have been quoted from the original source wherever possible.

There are introductory tables of atomic weights, physical constants of elements, etc. (47 pages). Then follow tables for the calculation of volumetric analyses (30 pages) and gas analyses (18 pages), physical constants of inorganic compounds, organic compounds, alkaloids and essential oils, and melting points and composition of lead-tin-bismuth-cadmium alloys (280 pages), specific gravity tables (64 pages), equivalents of weights and measures (10 pages), thermochemical data (12 pages). All this is excellent and very useful, though one might wish to have the thermochemical part considerably enlarged.

The book is concluded by a review of chemical literature and new books. This is well prepared. But as the review covers only "the more important articles" and is therefore acknowledged to be incomplete and as this information is easily available elsewhere (for instance, in "Chemical Abstracts"), the editor may find it useful to drop this part of the book when he needs the space for more tables in later editions. As it is the size of the work is just within the limits of a handy handbook. To enlarge the volume would make it without doubt unhandy.

Besides the editor, Dr. J. C. Olsen, the list of contributors includes Dr B. B. Boltwood, Dr. V. J. Chambers, Dr. C. A. F. Kahlbaum, Dr C. H. Lips, Dr J. L. R. Morgan, Dr. E. E. Reid, Dr A. Rogers, Mr. A. F. Seeker, Dr. A. Seidell and Mr. W. C. Whipple.

The Conquest of the Air by the Chemist.

If we leave aside early and isolated experiments, the endeavor of the chemist to transform the inert elemental nitrogen in atmospheric air into some nitrogen compound of commercial value, has extended on a systematic basis and on a relatively large scale over a little more than the last decade. This issue contains two articles particularly interesting with respect to the Birkeland-Eyde and Badische Company plants in Norway and the new Pauling plant in France for the production of nitrates by arc discharges. The more we learn of the different processes—differing essentially in the type and design of the arc furnace employed—the more it appears that with respect to the yield of grams of fixed nitrogen in form of HNO_3 per kw-hour there is not much of a choice between them; hardly much if any progress has been made in this respect over the unlucky Niagara Falls pioneer plant of Bradley and Lovejoy. Perhaps this is not so very astonishing since in the essential principle all the processes are alike.

But progress has been made in raising the concentration of NO in the gas mixture which leaves the furnace, and very much progress in simplifying the design. Without making any hideous comparisons, the enormous advance made in simplifying the construction is evident: this must find its expression in dollars and cents in the first cost of the plant. How important this is for a new industry will be clear to anybody only slightly acquainted with the ways of capitalists, who are, after all, very human beings like the rest of us.

With respect to the yield of fixed nitrogen per kw-hour we may compare the nitrate process with the calcium cyanamide process, which, though essentially different, is also a method of atmospheric nitrogen fixation. If 1 kw-hour produces 70 grams HNO_3 it binds 16 grams of nitrogen. On the other hand, in good commercial cyanamide practice 1 kw-hour binds some 70 grams of nitrogen in form of cyanamide. Naturally such a comparison, though interesting, is quite one-sided.

In a recent discussion before the New York Section of the American Electrochemical Society Dr. M. Loeb pointed out that as the formation of NO from air at the temperatures of the arc represents equilibrium, the attempt should be made to remove the NO in some way from the air by absorption in some suitable body so that in order to re-establish equilibrium new NO would be formed, etc. Dr. Whitney pointed out that such absorption might be very difficult at the enormous temperature of the arc. Yet the principle is plausible. In Haber's synthesis of ammonia—another instance of fixation of atmospheric nitrogen—such absorption is carried out and makes the process really practical. But here we work in the cold and absorption is comparatively easy. Clearly, the whole subject is in a state of evolution. It was first vigorously attacked by electrochemists with their inborn insurgent spirit. It is now being taken up by conservative business men. Such a combination must prove invincible in the end.

The Tremendous Magnitude of Western Copper Operations.

During 1910 no metal was the subject of such earnest and careful thought as copper. Overproduction, which had been freely predicted, finally became so great that insistent demands were made upon producers to reach some agreement for curtailment of output. One of the large determining factors was the tremendous development of Western low-grade copper properties, commonly spoken of as the porphyry coppers, which permitted operations on so large a scale that great quantities of copper were available at the remarkably low figures of 7, 8 and 9 cents per pound. The unquestioned ability of these companies to produce largely and cheaply, and the preparations being made by similar companies to enter the list of producers during 1910 and 1911, placed the prospects for the copper market in a bad light. Curtailment was necessary, and was accomplished in some measure, about 10,000,000 pounds per month, although the net result was not as encouraging as had been hoped for. Curtailment was urged as the best temporary method of dealing with a bad situation, for the well informed knew it to be a statistical fact that low prices of themselves would not curtail production and that it would be foolish to continue normal or increased production in the mere hope of a recovery of prices and the probability of causing considerable copper to be sold at a loss.

The development of the Western coppers was an important factor for another reason. On account of the character of the deposits and the nature of the treatment, it was possible to place them on a sound financial basis as investments, making them partake more of the nature of an industrial or manufacturing enterprise with known quantities of raw material and fixed costs of production than was usually possible in a mining venture. In brief, it was possible by calculation to see the end from the beginning and determine the probable life of the business. Furthermore, by combining in one company or group of associated companies the mining, concentrating, smelting and transportation features of the business, the profits of each transaction contributed to the net result.

The Utah Copper Company is the largest present producer of copper concentrate. Originally owning two plants, it later acquired that of the Boston Consolidated and then dismantled the smaller of the original two. The original Utah copper mill at Garfield, Utah, had a daily capacity of 6000 tons of ore averaging 2 per cent copper. Improvements made since then have raised this to 10,000 tons, which is the official figure given in the company's last quarterly report. The Boston Consolidated mill had an original capacity of 3000 tons per day, but after its acquisition by the Utah Copper Company it was wholly remodeled so that its capacity was raised to 6000 tons. This gives the Utah company a total capacity of 16,000 tons of ore per day, with the possibility of forcing the tonnage to a higher figure. Operations of such magnitude become a forcible factor in any field, and when it is considered that the cost of production after smelter deductions are made is from 7½ cents to 8¼ cents per pound of copper, it readily will be understood why a policy of curtailment was inaugurated awaiting the normal recovery of the market.

The Nevada Consolidated Copper Company, operating in White Pine County, Nevada, concentrates its ore in the Steptoe Valley mill and is at present treating about 5000 tons of 2 per cent ore daily. If plans are carried out it will eventually have a daily capacity of 15,000 tons. It is constructed in units of 1500 tons capacity, and 10 such units are embodied in the plans for the complete plant. The cost, as given in the reports of the company, is about 7.9 cents per pound of copper produced, after crediting the cost of copper with the income from the railway and from investments in two associated companies.

The Ray Consolidated Copper Company, Arizona, is one of the porphyry coppers which has not yet come into production, but it gives promise of being a large factor. The assured ore in Ray properties has been brought up to 59,000,000 tons, and the acquisition of the stock of the Gila Copper Company adds about 16,000,000 tons, or a total of more than 75,000,000 tons of 2 per cent copper ore. The mill under construction is planned to have a capacity of at least 8000 tons of ore per day, which should give an annual smelter output of 80,000,000 lb. of refined copper. This present estimate may be increased as development proceeds, for in the company's first report it was stated that the mill would have a daily capacity of 5000 tons, and this figure has now been exceeded. The estimate of cost is not in excess of 9 cents per pound of copper.

The Chino Copper Company will operate in New Mexico and is expected to commence production early this year. Its developed tonnage is 19,000,000 tons of 2.59 per cent copper ore, which is exceptionally high grade for deposits of this character. The concentrating plant is designed to treat 3000 tons per day, but, as has been the case with other mills of this character, the estimate probably will be exceeded. On this basis, however, the company will add from 35,000,000 to 40,000,000 lb. of copper to the 1911 production at a cost not over 9 cents.

The newest copper prospect of the first magnitude is the Inspiration, near Globe, Ariz. The ore is a disseminated deposit about 180 ft. thick. The tonnage which has been proved is 19,000,000 tons of 2 per cent copper ore, and this on an area of only 29.9 acres of land. An experimental mill of 75 tons daily capacity is practically completed, and from the results therein obtained will be planned a mill of 5000 tons daily capacity. Undoubtedly the Inspiration will join the goodly company of low-cost producers mentioned above.

The advent of all of these Western companies into the field under full production will be a factor to be reckoned with. It was pointed out a year ago that their output would be taken care of in the normal course of trade if a policy of curtailment were inaugurated to materially reduce visible stocks before the full flood of Western copper began to find its way into the market, but even now signs are not wanting that a copper convention must be entered into if the integrity and prosperity of the copper industry are to be maintained.

Double-Stage Crushing.

In double-stage crushing as practised on the Rand the stamp has been held in higher esteem than the tube mill as a mechanically efficient machine. The supporters of the tube mill have pointed out, however, that in usual practice the stamp is favored by receiving material which does not require reduction in the first stage, or rather, which is already reduced, while the tube mill is discriminated against by charging it with all the material requiring second-stage reduction.

In this connection recent experiments in South Africa by E. H. Johnson have shown a remarkable performance in double-stage crushing. By first separating the fine ore from the stamp feed and delivering it direct to the tube mill he has obtained from 10 stamps and one tube mill a duty of 26.1 tons per stamp in 24 hours, and a final pulp containing 0.5 per cent remaining on a 90-mesh screen.

Compared with single-stage crushing by stamps and fine screens, the above combination showed an increase of 32 per cent in horse-power efficiency and 31 per cent in grinding efficiency. This indicates possibilities for the tube mill which have not yet been fully appreciated, and which will tend to place double-stage crushing on a firmer basis than ever. As a fine comminuter the tube mill is practically sure of its position in any system of stage reduction, regardless of the machines which may be used in connection with it. Differences of opinion exist regarding the value of stamps as coarse crushers, and some metallurgists believe that rolls and chilean mills would serve the purpose better, but in regard to the tube mill opinion is hardly divided.

Some Handicaps to Iron Exports.

Considerable satisfaction is felt over the fact that our exports of iron and steel products in 1910 made a new record for tonnage by fully 15 per cent, the total of scrap, pig iron, unfinished steel, finished rolled steel, wire products, pipe, etc., amounting to about 1,540,000 gross tons, against a previous record of 1,325,740 tons, made in 1906. Of course, every step forward is a gain, but our export movement is still very small compared with our production. Much of the material exported is well advanced in stage manufacture, the declared value averaging about $40 per gross ton, and the tonnage of pig iron represented in our total exports is considerably in excess of 1,540,000 tons, perhaps 1,700,000 tons, but that is only 6 per cent of our total production in 1910.

Now, 6 per cent is a pretty low figure in view of the fact that in the Lake Superior region we have, as is generally admitted, the finest series of iron ore deposits in the world, and that in the Connellsville region we have as fine coking coal as is available anywhere, and elsewhere we have coal which in the by-product oven makes an entirely satisfactory coke. Copper, with which Nature has also bountifully supplied this country, we export very largely, as contrasted with the meager 6 per cent which obtains in iron.

The divergence in the movement of iron and copper suggests that our iron exports are not what they might be under better domestic conditions, and a glance at the world movements in iron confirms the suggestion. For we observe England making about 10,000,000 tons of pig iron a year and Germany 12,000,000 to 13,000,000 tons, and each exporting about 4,000,000 tons of iron and steel products, or from six to seven times as large a percentage of the production as we export of ours. These countries labor under certain disadvantages. England brings much of her ore from over the sea, her own ores being relatively lean, while Germany's ores are lean and far from tidewater.

It is true that our exports are in a measure restricted by commercial considerations. Our iron and steel export movement is not a "dumping" process but a regular commercial operation. Once our iron and steel exports were strictly of a dumping character, when they took the form chiefly of pig iron, steel billets and sheet bars and rails. In recent years a fairly definite understanding has been built up in the international markets whereby better prices, relative to manufacturing conditions, are obtained than formerly, and our exports cannot suddenly be increased without disturbing the markets, to the disadvantage of ourselves as well as of those sellers whom we should thereby displace. Nevertheless, our exports would have grown more rapidly had we not been subject to certain serious handicaps, the chief of these being the high freight and high labor costs.

There is little doubt that we are at the peak in the curve of labor costs in the United States. It is not reasonable to suppose that the constant increase for a dozen years presages a similar advance for another dozen, and the law of compensation seems even now to be preparing to effect an adjustment. To the iron and steel industry, however, relatively little relief is to be expected, for the movement to shorten hours and provide injury and death reliefs promises a counter influence.

In the matter of reduction in cost of transporting materials some relief is promised as the years pass. The suggestion may sound strange at the moment, when the railroads are so strenuously insisting that they must have higher freight rates in order to maintain their position, but we speak of adjustments as between commodities. A peculiar position prevails as between the railroads and the iron and steel producers. The railroads were long the iron trade's best customers, and in the eighties at least the railroads easily consumed 60 per cent of the product of the iron industry. In the nineties they consumed nearly as large a percentage, and their purchases up to the early part of 1907 were also large, though much smaller, in point of percentage, than in the eighties.

Through the fact of the railroads being the iron trade's best customers and through the movement of iron and steel materials being of a mixed character, it came about that freight rates upon these materials were established at a higher level than would likely be selected were the whole problem to be worked out in the light of present-day conditions. The ton-mile rates paid by the iron and steel industry upon ore, coal, coke, limestone, pig iron, unfinished steel and finished steel average fully as high as the average of all rates paid upon all freight moved over the railroads of the country. This is unnatural. The commodities involved are among the least subject to injury, and are among the most easily handled, of all freight. Enormous tonnages are moved in steady processions, frequently in solid trains involving the minimum expense. Of the value of a ton of finished steel at seaboard ready for export the freight paid in producing it forms a very large part, and there is reason to hope that in course of time this part will be reduced, so that the iron industry will pay no more than its fair share of the expenses of the railroads in conducting their operations.

We do not wish to be understood as intimating that American railroads would suffer by a comparison with those of other countries, for that is not our belief. But we do not think that at present the iron industry is enjoying its full share of the economies effected in American railroading, whereby they are able, as we understand, to stand comparison with English and continental European practice.

Minnesota Meeting of the American Chemical Society.

The forty third general meeting of the American Chemical Society, held at Minneapolis, Minn., from Dec. 28 to Dec 31, was attended by 275 members and guests and, like all recent meetings of the Society, it was an echo of the general enthusiasm that pervades its membership.

Owing to the fact that over 175 papers were presented, it was necessary to hold meetings of all of the Divisions and the meetings of the Division of Agricultural and Food Chemistry, Division of Fertilizer Chemistry, Division of Pharmaceutical Chemistry, Division of Industrial Chemists and Chemical Engineers, Division of Physical and Inorganic Chemistry and Division of Organic Chemistry were well attended.

A point especially worthy of note was the success of the Biological Section under the chairmanship of Dr Carl L. Alsberg, of Washington, D. C. Forty-four papers were presented before this section of a strictly chemical nature bearing upon biochemical problems.

The meeting of the Section of Chemical Education, held at a time when all the industrial chemists could meet with them, proved decidedly interesting and the discussion was general.

On the first day of the meeting the chemists all gathered in general session to listen to eight general addresses as follows:

The Lost Arts of Chemistry, by W. D. Richardson.

The Basis of Industrial Efficiency, by A. D. Little.

Synthetic Metals from Non-metallic Elements, by Herbert N. McCoy

Progress in Food Chemistry, by H. E. Barnard.

Mechanism of Cell Activity, by Carl L. Alsberg.

Waste Wood and Some of Its By-Products, by Geo. B. Frankforter.

The Formation of Carbohydrates in the Vegetable Kingdom, by Wm. McPherson.

The Efficiency of the College Graduate in the Chemical Industry, by Chas. F. Burgess.

The address of the retiring president, Wilder D. Bancroft, on "A Universal Law" was an exposition of the general application of the theorem of LeChatelier to all kinds of natural phenomena as well as those of a chemical nature.

Possibly the "complimentary smoker" in the rooms of the Commercial Club was as thoroughly enjoyed as any one feature of the meeting, for an unusually witty program had been arranged and original songs bearing upon individual chemists and chemical phenomena were thoroughly enjoyed; also the mementos furnished to the visiting chemists were pleasing to all. This, however, was not the only social function of the meeting, for several receptions and teas were arranged for the ladies and the banquet on Friday night, which was attended by some two hundred members, was also graced by their presence.

On Saturday afternoon a large number were treated to a sight seeing trip covering both the cities of Minneapolis and St. Paul. A number of the chemists also had the privilege of viewing the wonderful paintings of La Farge in the State Capitol of Minnesota. Excursions were made to the following works Russell-Miller Milling Company, Pillsbury Flour Mills Company, Washburn-Crosby Company, Consolidated Milling Company, Minnesota Linseed Oil and Paint Company, Archer-Daniels Company, Midland Linseed Oil Company, St. Anthony Falls Water Power Company, Cream of Wheat Company and International Stock Food Company.

The announcement of the election of Professor Alexander Smith as President of the Society and of Dr Louis Kahlenberg, Dr. Frank K. Cameron, Dr. Geo. B. Frankforter, Dr. F. C. Franklin and Dr. E. G. Love as Councilors-at-Large met with hearty approval and applause

Prof. M C Whitaker was elected editor of the *Journal* of Industrial and Engineering Chemistry and the report of a committee recommending a decided broadening of the policy of that journal was adopted.

The Secretary, Dr Charles L. Parsons, Durham, N. H., announced a net gain of 550 members for the year, the Society now having a membership of over 5100.

Inventors' Guild.

In the early part of 1910 several men who had done work along the line of invention and who, in developing and patenting their inventions, had come to realize the difficulties and disadvantages under which the inventor labors, instituted a movement for the formation of a society looking toward the betterment of these conditions. The result of this movement was the formation and incorporation in New York City of the Inventors' Guild, the object of which is briefly outlined in the following quotation from the constitution of the society.

"The object of the guild is to advance the application of the useful arts and sciences, to further the interests and secure full acknowledgment and protection for the rights of inventors, to foster social relations among those who have made notable advances in the application of the useful arts and sciences."

Some of the handicaps to which the inventor is subject, other than the proverbial one of never having any money, are the delays in the Patent Office and the ineffectiveness of its work, due to overcrowding and lack of proper facilities in the Patent Office; the expense and tardiness of litigation and the possibility under which a rich corporation, by delaying and prolonging a suit, may increase the expenses to a point which makes such suits prohibitive for a poor inventor; the disadvantage to which the American inventor is subject in foreign patent offices as compared with the liberality of the American Patent Office toward the foreign inventor, and many other conditions militating against the American inventor which should be remedied.

The membership of the Inventors' Guild is limited to 50. The idea of limiting the membership is that with a small society of this sort it is easier to accomplish real results than with a larger organization, hampered as it must be by unwieldiness and red tape. Further, with a small organization each man will feel that he is a working unit and that he will be depended upon to do real work, whereas in a large organization the general feeling is that there will be plenty of other men to do the work, and that lack of assistance from any particular member will make little if any difference. The result is that in the large organization the work, if any, is usually done by even a smaller number of members than that provided for in the Inventors' Guild.

It is proposed to select the membership of the guild carefully, and to this end a member must be formally proposed by a member of the guild, must be personally known to five members of the guild, must pass the membership committee and board of governors, and finally must be voted upon by the whole membership, 4 per cent of the votes cast being sufficient to reject a candidate. The object of such discrimination is to include among the members of the guild men who not only have made inventions, but who have achieved some measure of success in connection therewith, and who will therefore be capable of exerting some influence; and also that no one shall be admitted not congenial to practically the entire membership.

The officers of the Inventors' Guild are as follows: Ralph D. Mershon, president; Chas. W. Hunt, first vice-president; Chas. S. Bradley, second vice-president; Thomas Robins, secretary, and Henry L. Doherty, treasurer.

At the present time the guild has 29 members, as follows: Bion J Arnold, Dr. L. H. Backeland, W. H. Blauvelt, Chas. S. Bradley, Alex. E. Brown, Henry L. Doherty, Thomas A. Edison, Carleton Ellis, Stephen D. Field, James Gayley, Edward R. Hewitt, Peter Cooper Hewitt, Chas. W. Hunt, Dr. John F. Kelly, T. S. C. Lowe, Ralph D. Mershon, Ambrose Monell, Dr. Edwin F. Northrup, Prof. G. W. Pierce, Chas. E. Pope, Dr. Michael I. Pupin, Thomas Robins, Dr. F. Schniewind, C. H. Smoot, Prof. Carl Thomas, F. L. O. Wadsworth, Arthur West, Dr W. E. Winship, B. F. Wood.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our London Correspondent.)

Magnetic Properties of Iron and Its Alloys.

At a meeting of the Institution of Electrical Engineers early in December, Sir ROBERT A. HADFIELD and Prof. B. HOPKINSON presented a paper on "The Magnetic Properties of Iron and Its Alloys in Intense Fields." The materials for the research carried out by the authors were a series of alloys prepared at the Hecla Works, which had already been extensively investigated and many of their physical properties had been ascertained. They included iron-carbon steels, nickel steels and manganese steels in varying proportions.

The most important results obtained were: (1) Every alloy has a different saturation intensity of magnetism, which occurs mostly in a field of 5000 units, but in a few there is a slight increase between 5000 and 25,000. All the materials exhibit the behavior of a mixture of magnetic substances with non-magnetic substances, the permeability of which does not vary materially from unity. The non-magnetic or nearly non-magnetic nickel and manganese alloys show no exception. In none of the alloys examined does the permeability differ from unity by much more than 2 per cent. (2) There is in the series no alloy having a higher specific magnetism than pure iron. (3) The saturation value for pure iron of specific gravity 7.8 is 1675 absolute units, within 1 per cent. (4) In an annealed iron-carbon steel containing a small proportion of other elements the specific magnetism is less than that of pure iron by a percentage equal to six times the percentage of carbon. It is deduced that the magnetism of carbide of iron is about two-thirds of that of pure iron. (5) Quenching an iron-carbon alloy from a high temperature largely reduces this specific magnetism, but the amount of reduction is rather uncertain. (6) The addition of silicon or aluminium to iron reduces the specific magnetism nearly in proportion to the amount added, as if the addition behaved as an inert diluent; but if carbon is present silicon appears to neutralize its action to some extent. (7) In the case of alloys of iron with nickel and with manganese, or with both, no simple relation between their magnetism and composition has been observed. This might be due to the peculiar effects of heat treatment on these alloys. The authors, in conclusion, direct attention to the following general points: Among the alloys there are only one or two whose magnetism is greater than the sum of the magnetism of the separate constituents, a specimen containing 11.4 per cent of nickel being especially noticeable. Secondly, the magnetic properties of every alloy, even those which are almost non-magnetic, are very closely expressed by the equation $B = H + 4\pi I$, where I is the constant designating magnetism, provided that H exceeded 7000 C.G.S. units. Thirdly, comparison with Barrett's results in a field of 40 units, or less, shows that in some cases the magnetism of an alloy may be considerably greater, relative to that of pure iron, in low than in high fields. Barrett found that when the value of H is small several silicon-steels and one aluminium-steel are more magnetic than pure iron; but all these materials are less magnetic than pure iron when saturated. In these cases the coercive force is small. In some alloys with a very high coercive force, such as some of the manganese steels, the magnetism relatively to pure iron is much greater when saturated than in a field of 40—in some cases more than twice greater.

The discussion of the paper was opened by Prof. Silvanus P. Thompson, who said the facts put forward were a strong confirmation of Ewing's theory that the saturation value of intrinsic magnetism was practically a constant. If the research had done nothing beyond establishing the fact that the magnetic behavior of iron is as that of the sum of its constituents, yet a most important point would be established.

Mr. J. T. Morris thought that the research would materially assist in setting up a sound theory for the guidance of experimental work. The influence of temperature was most important. It was interesting to know that this point was now under investigation.

Professor Hopkinson in his reply said he hoped it would be possible to investigate the phases of iron by the magnetic properties of the metal. In the case of annealed carbon-iron alloys he thought it had been shown that the magnetism was a function of the amount of carbon. He did not think that the iron carbide was affected by the presence of iron; and it was clear, both from chemical and microscopical results, that in such alloys they were dealing with mixtures. As to the effect of temperature, he could say that in the case of pure iron a rising temperature lowered the saturation intensity. The reduction increased up to the critical point of 750° C., when the magnetism suddenly disappeared. It seemed probable that temperature affected the molecular constituents; and the question arose whether the reduction of magnetism resulted from the total destruction of the magnetism of certain molecules or whether it was consequent on a gradual change taking place in the whole. He thought the former explanation was more probably correct

Non-Ferrous Alloys for High-Pressure Castings.

At a recent meeting of the Institution of Mechanical Engineers, Prof. H. C. H. CARPENTER and Mr. C. A. EDWARDS contributed an interesting and valuable paper on "The Production of Castings to Withstand High Pressures." The first experiments were made with pure gunmetal containing 85 per cent of copper and 15 per cent of tin, a small quantity of copper phosphide being subsequently added to remove oxygen and leave not more than 0.1 per cent of phosphorus. With this alloy the authors repeatedly reproduced perfectly sound castings which, after being machined, withstood an average pressure of 18 tons before they burst.

Experiments with aluminium bronze followed. The first alloy contained 91 per cent of copper and 9 per cent of aluminium, and the mixture was poured at 1125° C., or about 80° above its solidifying point. Only one unsuccessful casting was obtained out of six. After machining they were tested up to 12 tons to 13 tons, when slight stretching ensued and water came through the valve joint; but by tightenng up the joints the pressure could be raised to 14 tons to 15 tons, when further stretching resulted; but, after again tightening up, the pressure was increased to 18 tons, at which none of the four castings fractured. Consequently, 9 per cent aluminium bronze was capable of withstanding as high pressure as 15 per cent gunmetal; and, moreover, the former had greater ductility.

Up to this point all the castings had been made in iron chills. Further castings were made in green-sand molds, the pouring, as before, being from the bottom. Three castings failed to pass the preliminary test, and the other three were tested up to 10 tons when tightening of the joint was necessary. At 13 tons it stretched again, and, with alternate stretching and tightening of the valve joint, a pressure of 19 tons was attained. The walls were then machined down to varying thicknesses and further experiments carried out which appeared to indicate that if these tests had been carried far enough the cylinders would only have been fractured after the hardening produced by the water pressure had raised the yield stress to the same figure as the ultimate stress.

These results showed that cylinders of aluminium bronze could be cast, both in chills and in sand molds, to withstand a water pressure of 18 tons per square inch, but they had the disadvantage of beginning to stretch at a pressure of 10 tons to 12 tons—the sand casting giving the lower figure. A bronze containing 9.5 per cent of aluminium stood up to 11 tons before bulging, and a 10 per cent bronze was tested up to 12.5 tons before any expansion, while 10.5 per cent bronze stood up to 14 tons before any tightening was necessary. Finally, an 11 per cent aluminium bronze allowed hydraulic pressure to be taken up to 26 tons without any sign of leakage.

In their summary the authors stated that conditions had been

worked out for the production of non-ferrous hydraulic castings capable of withstanding pressures of from 14 tons to 20 tons. These results had been obtained with pure copper-aluminium bronzes containing 9 per cent to 11 per cent aluminium. Their largest experimental castings weighed 36 lb., including gate and riser, and the best proportion of aluminium for these was 9 per cent to 10 per cent. For smaller castings a higher percentage could be employed. The essentials for success were (1) very slow pouring; (2) casting at a temperature not higher than 50° C. to 80° C. above the initial freezing point; (3) the metal must enter the mold at the lowest possible point; (4) green-sand molds must not be too damp, and with close sand the lower part of the mold should be dried; (5) with large castings risers must be used to overcome shrinkage. The average of clean, sound castings was not less than four out of six. Their homogeneity appeared perfectly satisactory, and their corrosion in fresh or in sea water was extremely slight. So far as the authors were aware, no other bronzes possessed this combination of properties.

The discussion was opened by Mr J. Archbutt, of the Midland Railway, who remarked that the paper brought out the importance of attention to small details for the production of good castings. He wished to ask why the authors selected the 15 per cent tin alloy, which was very brittle. Quenching at above 500° C. had a very great influence on the properties of this 15 per cent alloy.

Mr. Bateman said his experience of hydraulic pressures for valves showed that phosphor-bronze would stand three times the working pressure for a long time, while ordinary gunmetal would stand that pressure for only a few weeks.

Mr. Harrison pointed out that commercial engineers had to adhere very rigidly to specification for such customers as the Admiralty. He had found that the metal put into a large casting amounted to 15 times the weight of the finished article.

Mr. C. A. Edwards, in the course of his reply, said it was better to use a big head and ensure a good casting. In the pressure tests they filled the castings with water and pumped up the pressure on top with oil. They had tried quick pouring, and that was why they had so many bad castings at the outset. As to adhering to specifications, if castings would stand higher pressures and be perfectly safe the users should not quibble about other matters.

The Estimation of Phosphoric Acid.

At a recent meeting of the Society of Public Analysts Mr. G. F. Wesley Martin described a new method. The phosphoric acid is first precipitated at ammonium phosphomolybdate, which, after washing, is dissolved in excess of caustic alkali, and the ammonia is then distilled into excess of standard acid and titrated in the usual way. This method has the advantage of fair rapidity, and appears to be sufficiently exact.

Market Report.

December, 1910.

Copper. Opening at £57.5.0 copper remained fairly steady until the close of the month when it showed a downward tendency, closing at £52.15.0.

Tin opened at £169.15.0 and rose smartly to £175 by the 12th, thence dropping to £171.10.0 by the 21st. After this recovered to £175.10.0 (28th).

Lead has been practically fixed at £13.11.3.

Hæmatite opened at 64/6 and appreciated slowly to 66/11½ (28th), the rise being more pronounced after the 9th.

Scotch Pig opened at 55/9 and has kept fairly steady, dropping slightly on the 6th and 13th. Closed at 55. 10½.

Cleveland Warrants opened at 49/9, and with the exception of small fluctuations, on the 6th and 13th, have remained steady, closing at 49/10.

Sulphate of ammonia, f.o.b. Liverpool, per ton	£12	17	6
Alum, lump, loose, per ton	5	12	6
Antimony, black sulphide powder, per ton	22	..	..
Borax, British refined crystal, per ton	16	..	..
Sal ammoniac, lump, firsts, delivered U. K.	42	..	..
Copper sulphate, per ton	19	15	..
Camphor, 1-oz. tablets	..	1	7
Caustic soda, ash, 48 per cent, ordinary, per ton	5	10	..
Shellac, standard, T. N., orange spots, per cwt.	4	4	..
Sulphur, recovered, per ton	5	..	..
Carbolic acid, liquid, 97/99 per cent, per gal.	..	1	1
Hydrochloric acid, per cwt.	5	..	
Creosote, ordinary good liquid	..	..	2
Naphtha, solvent, 90 per cent at 160° C., per gal.	..	..	10
Petroleum, Russian, spot, per gal.	..	..	5½
Copper ore, 10 per cent to 25 per cent unit	9/1½ to 10/1½		
Tin ore, 10 per cent, per ton	£110 to £111		
Mica, small slab, in original cases, per lb.	6d to 1/-		
Litharge, flake, per ton	£15	15	..
Red lead, genuine, per ton	16	5	..
Bleaching powder, 35 per cent. per ton	4	5	..
Platinum, per oz. nominal	8	..	..

India Rubber, Para fine, opened at 6/3½, had dropped by the 7th to 6/1½, and thence to 5/10½ on the 14th and to 5/10 by the 21st, ultimately closing at 5/9 per lb.

Compared with prices for the end of December the following have appreciated:

Antimony has risen per ton	£2	..	..
Copper sulphate	..	5	..
Shellac, per cwt.	..	1	6
Carbolic acid, per gal.	..	..	1½
Creosote, per gal.	..	..	⅛
Naphtha, solvent, per gal.	..	..	½
Petroleum	..	..	¼
Tin ore, per ton	5	..	..
Litharge	..	10	..
Red Lead	..	10	..
Platinum, per oz.	..	6	..

Sulphate of ammonia only is quoted 2/6 cheaper.

London, England.

The Western Metallurgical Field.

Conservation in Metallurgy.

In discussing the efficiency of present metallurgical processes and the possibility of avoiding waste in their operation, Mr. Franklin Guiterman presented some forceful considerations in his annual address as retiring president of the Colorado Scientific Society. By way of introduction the speaker defined the meaning of the word "waste" on account of the "confusion which has arisen in the public mind from the reckless use of the word by superficial magazine writers and that brotherhood of doctrinaires which acclaims itself "conservationists." The waste of a product in whole or in part involves the sacrifice of something which might be profitably produced and which, if saved, could be of use to the community. It therefore follows that while waste is always non-utilization non-use is not necessarily waste.

The metallurgical industry is always at that state of efficiency which limits the further use of raw products of inferior grade, or which makes it inadvisable to carry the process to a higher degree of perfection, even if this be possible. Hence the "waste" of yesterday was due to limiting conditions which may be removed by the progress of to-day, while the improvements of to-morrow are anxiously awaited to reduce to-day's losses. In this sense so-called waste has been merely non-use, and many examples are available to show that the material which was not used years ago is to-day the source of remarkable profits due to improvement in processes of treatment.

An exceptional example of involuntary conservation of an unused product for over 20 years was the retention of some mill tailings from a Leadville mill. Cribbing was erected to prevent the tailing flowing onto neighboring property and into a stream. The product was the waste from concentration of a mixed sulphide ore, of which only the lead and iron content was then useful. The waste assayed Au, 0.04 oz. per ton; Ag, 6 oz. to 7 oz. per ton; Zn, 26 per cent to 27 per cent; Pb, 6 per cent

to 7 per cent; Fe, 20 per cent, and SiO_2, 8 per cent. The zinc ore, blende, was discarded for obvious reasons known to all lead smelters. To allow it to remain in the ore would have been to invite penalties which would have reduced profit to loss. Hence it was eliminated and only retained on the property unwillingly. Twenty years later, owing to the development of electromagnetic separation of pyrite and blende, the 80,000 tons of material in the dump netted the owners over $325,000.

This is probably not typical of anything that will occur 20 years hence with waste or unused products of to-day, for metallurgical progress is more rapid now, and, furthermore, any unused material which has a potential value is experimented with and, generally speaking, is always saved.

Among the unrecovered metals which are either lost in the metallurgical practice of to-day, or recovered only as a contaminating impurity of a more valuable product, are cadmium, bismuth and antimony. Cadmium occurs in almost all Colorado blendes in small quantities. It is a most useful metal for some purposes, but a detriment to its extended use is its high cost of production. Its tendency to rapid oxidation makes its recovery difficult and inefficient, and as it occurs only in small quantities as compared with the zinc, it is practically "wasted."

Bismuth and antimony are recovered in the blast furnace with lead, and contaminate it to the detriment of the price. Bismuth in amounts exceeding 0.4 per cent in lead excludes it from the market for corroding purposes, and the small amount of bismuth could, therefore, be well dispensed with. Here is an example of recovery of a product entailing a financial loss. The same applies to antimony occurring in lead ores, for it increases lead losses in refining and could be dispensed with to commercial advantage.

Another form of so-called waste which has been a fruitful field for those who like to reduce a loss to dollars and cents without regard to its other features is the elimination of sulphur during the smelting of sulphide ores. It would be possible to convert the sulphurous gases into sulphuric acid, but unfortunately there would be no market for this product under governing conditions. The smelters could produce more sulphuric acid in a day than is now made and sold by Western manufacturers in a month. As sulphurous acid is a gas which can be discharged into the air under proper precautions with comparatively little damage to vegetation, and as sulphuric acid is a liquid which must be contained in iron vessels, it is readily seen that the production of the latter would be a matter of large expense rather than of profit, and of serious embarrassment than of congratulation.

Arsenic also is contained in smelting ores, and is now recovered at little or no profit. If this element could be discharged to waste without damage its loss would hardly constitute a failure to observe the laws of conservation. When the time comes that the uses of arsenic warrant an increased production it can readily be supplied at short notice, but until then its recovery is hardly a commercial necessity as far as use is concerned.

Summing up, Mr. Guiterman believes that with respect to gold, silver, lead and copper, and the working costs obtaining in the processes, the limit of efficiency seems to have been reached. There is undoubtedly much room for improvement in the metallurgy of zinc, not only in point of metal recovery but also in the present high cost of smelting operations. But the glaring weaknesses in methods are to be found not so much in the larger as in the smaller enterprises, and it is in respect to the latter that the metallurgical engineer will be called upon to give his counsel and aid.

Progress in Copper Milling and Smelting.

At Needles, Cal., the United States Smelting, Refining & Mining Company has just completed and put in operation a 250-ton concentrator to handle low-grade copper ores. The company also has a smelting plant at Needles and the product of the concentrator will be treated locally.

The initial run of the first unit of the new Miami concentrator in Arizona was to have occurred in January, but delays incident to such a project have postponed operations until the present month so that the operation of the first unit may be coincident with this issue of Metallurgical and Chemical Engineering. The Miami is one of the large low-grade propositions that are being brought into production this year and is modeled on the lines which have proved satisfactory in older mills.

At the Garfield smelter, Utah, reverberatory copper smelting is being improved by running harder silica slags than were formerly considered standard practice. It has been customary to run lower silica slags in reverberatory furnaces than in blast furnaces, as experiment had shown that when silica rose above 38 per cent to 40 per cent in the former the capacity and efficiency of the reverberatory were decreased. Recently, however, reverberatory slags at Garfield have carried as high as 45 per cent silica, and at the Steptoe plant in Nevada as high as 43 per cent, with satisfactory results. This is made possible by exercising greater care in mixing and preparing the charge, and results in the advantage of reducing cost of operation and of fluxing material.

As previously stated in these columns, the California copper smelters have been operating at reduced capacity, or not at all, on account of injunctions obtained by the agriculturists requiring the smelters to abate the smoke and fume nuisance. The U. S. Smelting Company, at Kennett, put a bag house in commission, but it was able to handle the fumes from but two furnaces. Three had been tried but it was found impossible to cool the fumes sufficiently to prevent disintegration of the bags. Later reports, however, indicate that the system has been improved and that three furnaces are now in operation.

The First National Copper Company, owning the smelter at Balaklala, was closed pending the installation of the Cottrell process of electric fume condensation. It was expected that the plant would resume operations in January, as the necessary improvements would be installed by that time. The California metal production has suffered a serious setback as a result of the injunctions obtained by the farmers, and it is doubtful whether, under present market conditions for copper, some of the plants will resume operations with any kind of system of fume recovery.

Montana-Tonopah Mill Operations.

In the eighth annual report of the Montana-Tonopah Mining Company, operating at Tonopah, Nev., some data are given regarding the milling operations. During the year an average of 38.5 stamps out of 40 were dropping continuously. The tonnage milled was 50,245, and the average stamp duty was 3.67 tons per 24 hours. The average value of ore milled was $15.22 per ton (0.206 oz. gold and 21.139 oz. silver). The average value of tailing was $1.43 (0.0146 oz. gold and 2.168 oz. silver). The gross mill extraction was 90.8 per cent, and the cost of milling $3.37 per ton. The bullion produced cost 53.4 cents per ounce, and brought 67.4 cents per ounce.

The Non-Ferrous Metal Market.

With the exception of tin, all the metals suffered a reduction in price during the past month, and while fair business has been reported in all lines, only tin has enjoyed a heavy trade. The prospect for any material change is not considered good.

Copper.—It is generally believed that practically all the business transacted in sales of this metal has been consummated at concessions in price. Even the agencies which have been holding aloof from the market have shown a tendency to enter at current prices. Lake copper is quoted at 12⅝ to 12¾c and electrolytic at at 12.35 and 12.40c.

Lead.—A fair business has been transacted at the following prices: 4.32½ to 4.35c in St. Louis and 4.5c in New York.

Spelter.—Immediate and future deliveries of this metal have combined to make a fair volume of business. St. Louis prices have been about 5.35 to 5.37½c and New York 5.50 to 5.52½c.

Tin.—The continued strength of the foreign market has produced a local conviction that it is due to legitimate causes and buyers are entering the market more liberally. Prices rose somewhat during the month and the ruling price for the month was 30.5 to 40c.

The Iron and Steel Market.

The new year opened with the iron and steel industry running at between 40 and 50 per cent of capacity. Out of a total 33,000,000 tons, the capacity of blast furnaces nominally in blast was about 19,000,000 tons a year, but a capacity of 2,000,000 or 3,000,000 tons was banked to avoid accumulation of pig iron while the attendant steel works were idle. There had been a sharp slowing down during December, on account of seasonable conditions, but there has been relatively little speeding up during January and the gait at the close of January is little if any over 50 per cent of full.

A condition of extreme nervousness prevailed among buyers in December on account of widespread reports that prices of finished steel products might be reduced at the meetings of manufacturers which were expected to be held in connection with the dinner called for the night of Jan. 11. Among producers there was practically no expectation that any change would occur in prices, the dinner being intended rather to encourage adherence to established prices. After Jan. 1 orders began to come in more freely, chiefly in the form of specifications against contracts, and representing requisitions which had been held back to avoid complicating the annual inventories. After the dinner of Jan. 11, with its failure to develop any change in prices, the flow of business experienced further, although slight, improvement.

The total of January bookings in finished steel products promises to show a slight gain over December, and, as January production has been less than December, a gain in unfilled orders on books is likely to be shown. A test of this is furnished by the Steel Corporation's reports. During the whole of 1910 its unfilled orders decreased, but the December decrease of 85,656 tons was the smallest. The total on Dec. 31, 1910, was 2,674,757 tons, the smallest ever reported. A gain is expected to be shown during January of between 60,000 and 120,000 tons.

All expectations of lower prices for finished steel products in January were disappointed, while a surprise, at least to the general trade, occurred in the other direction, since effective Jan. 23 all wire products were advanced $1 per ton, making plain wire 1.55c, base, wire nails $1.75, base, painted barb wire 1.75c and galvanized barb wire 2.05c. The advance was effected by the leading interest announcing its new price, the independents promptly following suit. A conference between a few of the larger interests had previously been held.

The wire advance was made, as such wire advances frequently are, for the purpose of stimulating specifications. The large jobbers had previously been well covered by contracts, permitting specifications to be filed for 60 days, and toward the close of the period it will depend upon the condition of mill order books how much tonnage they will permit to be specified.

The wire advance of $1 a ton follows a decline of $3 a ton during the first seven months of 1910 and successive advances totaling $5 a ton after the great reduction of May 1, 1909, so that the new prices are $3 a ton higher than the lowest prices made after the great market break which started Feb. 10, 1909. Prior to the advance just made the wire mills were running very slack, much less than 50 per cent of capacity, but have been doing better since and will probably be running practically full by the beginning of March.

It seems to be the general opinion that the decline in activity has carried the iron trade well below the normal and that a marked upturn is a certainty, the time only being in doubt, and predictions of a distinct improvement have been made, naming all the dates from Feb. 1 to May 1.

Railroad buying showed a slight improvement in January and there are hopes of further improvement upon the settlement of the freight rate issue by the Interstate Commerce Commission. This is now expected not later than March 15. The Pennsylvania Railroad Company and the rail mills have at last agreed upon specifications for the 150,000 tons of rails for which the railroad offered orders for this year's delivery. This company has ordered about 2000 freight cars and a few other car orders have been placed. No very heavy railroad buying is expected, but a moderate improvement over conditions in the past eight months is to be expected, as many of the roads are short of equipment in one respect or another. There is no prospect of a big rail year. Orders thus far placed indicate a total of between 1,000,000 and 1,500,000 tons for replacement purposes on the steam roads, and with the various other demands the total rail production of the year bids fair to be between 2,500,000 and 3,000,000 tons, not far from the output in 1909 and contrasting with almost 4,000,000 tons produced in 1906, the record year.

Prices of finished steel products are being held quite well. There is occasional shading in one product or another by small interests, but the leading producers, including the Steel Corporation and some eight or ten independents, are holding their prices rigidly, and the attitude of these interests is that they will hold prices irrespective of occasional shading by smaller interests, but will abandon all reserve should any case develop of shading by any large interest. In other words, divergences from the present schedule will hardly prompt an attempt to make a fresh stand upon some level a little lower, but will provoke an open market.

Pig Iron.

Prices have yielded to the extent of about 50 cents in the Philadelphia, Buffalo and Chicago markets, the Pittsburg and Alabama markets being unchanged. There was heavier buying in January than in December, but chiefly by the action of a few consumers who make a practice of buying at this particular time. Merchant pig iron stocks are still accumulating, on the whole, but in some districts stocks are about stationary. Prices at valley furnaces, 90 cents higher delivered Pittsburg, remain as follows: Bessemer, $15; basic, $13.50; No. 2 foundry, $13.75; malleable, $13.50; forge, $13.25. No. 2 foundry is $15.50 at Philadelphia and $14 at Buffalo, No. 2 being $14.25 at Cleveland, $15.50 at Chicago and $11 at Birmingham.

Steel.

Very little business has been done in billets and sheet bars on account of so much tonnage being held over on contracts which should have expired Dec. 31. Prices are very well held on the basis of $23 for billets and $24 for sheet bars, Bessemer or open-hearth, f.o.b. Pittsburg or Youngstown. Forging billets are $28, Pittsburg, with the corresponding price of $30.40, Philadelphia, nominally quoted, while actual sales have been made at $27, Chicago. Rods are $27.50, Pittsburg.

Finished Steel.

Finished steel prices are unchanged, except as to wire products, and are as follows, f.o.b. Pittsburg except where otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, 1.40 cents for tank quality.

Shapes, 1.40 cents for beams and channels, 3-inch to 15-inch inclusive, zees and angles 2 x 3 and larger.

Steel bars, 1.40 cents, base; iron bars, 1.35 to 1.40 cents, Pittsburg; 1.30 cents, Cleveland; 1.30 cents, Chicago.

Wire nails, $1.75, base, per keg; plain wire, 1.55 cents, base; painted barb wire, 1.75 cents; galvanized barbed wire, 2.05 cents.

Black sheets, 28 gage, 2.20 cents; galvanized, 3.20 cents; blue annealed sheets, 10 gage, 1.65 cents; painted corrugated roofing, $1.55 per square; galvanized, $2.75 per square.

Tin plates, $3.60 for 100-lb. cokes.

CORRESPONDENCE

Copper Poisoning.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—We have just had an experience here that seems to warrant the publication of this warning to any one who contemplates working with copper in the electric arc furnace.

We melted 5000 lb. of electrolytic copper scrap—uncontaminated except for a small amount of admixed iron—in a three-phase arc furnace of the ordinary steel furnace type, the experiment lasting some five hours. A few hours after pouring off all of the ten men in the furnace building suffered inconvenience in breathing. For the 24 ensuing hours severe nausea was experienced in each case and a soreness throughout the entire system similar to that of acute grippe.

Since in all other respects the run resembled an ordinary steel run, I attribute the trouble we experienced to copper which was shown to be present in the furnace fumes. The temperature of the copper bath as a whole at no time exceeded 1300° C, so that probably the copper was volatilized only at points directly beneath the electrodes.

From the severity of the attack, coupled with the short time we were exposed to the fumes, and that in a building which was well ventilated, I am of the opinion that very serious results might obtain under less favorable conditions.

I also attach more importance to the above from the fact that in five years of continuous research work on a large scale with furnace processes which involved, among others, tellurium, tellurides, arsenic, arsenides, zinc and sulphide ores, the only physical inconvenience suffered has been an occasional carbon monoxide headache. C. A. HANSEN.

General Electric Company, Research Laboratory, Schenectady, N. Y.

The Origin of Hydrogen in Blast-Furnace Gas.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—In the July issue, 1910, of this journal the authors published an article entitled "A Quantitative Investigation of the Source of Hydrogen in Blast-Furnace Gas." Considerable interest was manifested in the contents of this paper, as it was demonstrated, from the basis of the authors' experiments, that the source of only about half of the hydrogen in the furnace gas could be identified. It will be recalled that the authors suggested that the remainder of the hydrogen in the exit gas might be due to the reaction of hot carbon with combined water in the burden, previously unexpelled by heat.

The above-mentioned article has been reviewed by H. Le Chatelier in the *Revue de Metallurgie* of October, 1910. The main feature of his paper is an explanation of the source of the remaining hydrogen, which he maintains is very simple. He states that the decomposition of water may be readily effected by carbon monoxide in the hot top gases according to the following reaction: $CO + H_2O = CO_2 + H_2$. Le Chatelier states that this reaction begins at 200° C. and occurs to a considerable extent at 300° C., the temperature of the top gas in the authors' experiments, and proceeds to show that at this temperature the entire water content of the gas must be dissociated if the gases are in equilibrium. He admits, however, that in this experiment only half the entire water introduced into the top of the furnace is dissociated, but concludes by stating that the amount would be greater the higher the temperature of the furnace top and the longer the gases remain at this temperature in passing through the mains to the gas-cleaning plant.

The writers have referred to the well-known work of Neuman and Pistor[1] and from their published statements, or from similar work by other authors, fail to confirm the figures in Le Chatelier's article. Neuman and Pistor passed steam and carbon monoxide through a porcelain tube heated to different temperatures and determined the carbon dioxide formed Their results are as follows.

Temp. in Degrees C.	Per Cent CO Converted into CO_2
560	trace
600	2 per cent
900	8 per cent
954	10.5 per cent

These results would show that but little hydrogen would be formed, according to the previously mentioned reaction, below 600° C. But hydrogen may be liberated from water by carbon at a lower temperature. According to Ledebur[2] the decomposition of water by solid carbon begins at 500° C., the product at that temperature being mostly carbon dioxide. From these results it would seem that water would be decomposed by solid carbon rather than by carbon monoxide, since the former reaction sensibly occurs at 500° C. and the latter not until 600° C. is reached.

It would also seem that no reaction could occur in the extreme top of the furnace or in the mains leading from the furnace. The average temperature of the top gas during the experimental work conducted by the authors was only 290° C. The moisture in the gas was not determined in this experiment. Many tests, however, showed the moisture content to vary from 7 per cent to 15 per cent by volume, the hydrogen being at the same time from 4 per cent to 5 per cent.

The recognized complexity of reactions in a blast furnace must cause the solution of the present problem to be difficult. (Even the conditions at the very top of the stock descending into the furnace may be subjected to a sudden change due to slipping.) The writers have been interested in this review by Le Chatelier, but do not think his statement is well substantiated by other published evidence obtainable.

Carnegie Steel Co., Duquesne, Pa. R. J. WYSOR and W. D. BROWN.

Electrode Construction for Furnaces.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—Your January issue, page 42, contains a short article by Dr. Mahlke on a new form of electrode which may involve some features of interest. Permit me to call attention, however, to the prevalent misconception, which I find also exists in this article, that a part of the furnace in which the current density is greater will necessarily be heated to a higher temperature. This is unquestionably an error, even though it has long been supposed to be true. I had called attention to it in some publications on the losses in electrodes.

It was there shown that the stable temperature which any part of the furnace will reach depends not only upon the heat set free in it, but also, and quite decidedly so, on the relative rate at which the heat thus generated internally, or reaching it from other places, will leave that particular part. It was shown that it was quite possible and practicable to use small electrodes with a very high current density, provided they are made so short that the heat will be led off as rapidly as it is formed, and in such a case the temperature will not rise higher than with small current densities.

It would be quite possible, therefore, that the polar enlargements proposed by Dr. Mahlke (and already existing in slightly different forms in other furnaces) could be heated to a higher temperature than the end of the electrode in contact with them, even though the cross-section of the enlargement is much greater than that of the electrode. All that is necessary is that the proportions be such that up to this enlargement all the heat generated in the electrode, and no more and no less, flows out at the cold end. The heat generated in the enlargements then cannot flow out through the electrode, and if it cannot

[1] *Berichte der Deutschen Chemischen Gesellschaft*, XVIII, p. 2894.

[2] "Gasfeuerungen," p. 69.

flow out into any other part as rapidly as it is formed it will accumulate and raise the temperature. Of course, when its temperature gets higher than that of the electrode then there will be a slightly increased heat flow through the electrode, whereby the portion of the enlargement immediately surrounding the hot end of the electrode proper will be slightly chilled by the electrode. It would therefore be possible (whether it would be practicable or not cannot be said off hand) to make this enlarged terminal very great in bulk and actually use it to generate much of the furnace heat, as the heat generated in it could be made to flow into the furnace product lying between these enlarged electrode terminals; the resistance of the product itself might then even be negligibly small. This, therefore, illustrates again the fallacy of our former conception that the temperature must be greater the higher the current density.

Concerning the practicability of his arrangement it must not be forgotten that the electrode generally burns away and must therefore be fed into the furnace; hence anything but a uniform cross-section would in many cases be impracticable. To use the enlargements at the end of electrodes in arc furnaces seems to me to be of theoretical rather than practical interest. It is quite true that the electrode losses in arc furnaces are greatly increased by the fact that the hot end generally has a very much higher temperature than the treatment of the product requires, as, for instance, in iron furnaces; yet to get over this difficulty by the proposed enlargements would probably introduce insurmountable practical difficulties; the furnace, for instance, would have to be opened to replace such an enlargement, not to mention the difficulties in screwing a piece of carbon with a carbon screw to the rounded end of a white hot electrode, from which the stump of the old screw must first be taken out without injuring the thread, all of which seems to be a practical impossibility.

Dr. Mahlke begins his article by saying that this point had been "overlooked" in recent articles on electrode losses. As far as I am concerned I certainly did not overlook it, but in fact even called attention to such enlargements and the possibility of higher temperature in them by referring to the pole plates in the Roechling-Rodenhauser modification of the induction furnace, although I have since then learned that these plates are not counted upon as heat producers.

Philadelphia, Pa. CARL HERING.

Technical Training.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—Co-operation, the slogan for the advancement of the age, hand in hand with specialization, has never before in history been carried on to so great an extent. In the commercial world specialists in each particular line work together toward an ultimate end. The same can be said of the educational world, especially as pertaining to higher education, yet, further, it has been extended to the high schools and, in a moderate degree to the grades. In fact, it has become a recognized principle. When, because of this spirit, such remarkable strides in progress have been made during the last century in each separate field, why, then, arises the question, have they not joined forces? This can practically be accounted for by a certain amount of suspicion with which a member of one fraternity looks upon a member of another. This, of course, has for a basis a slight foundation in that the scientific man's knowledge as to practical things, so thinks the practical man, is about on a par with the farmer's opinion of the city chap and vice versa.

However, the practical man, who has had a practical education and has not been afraid to soil his hands by beginning at the bottom of the ladder, and thus getting a working knowledge of affairs, is the nearest to a combination of the two which we have in this age. Yet, even this man, unless his training has been such as to form in him the student habit, will very soon become so engrossed in the immediate work at hand that he will fail to realize the advance that science is making, and that he is falling behind the procession. No matter how great a success he may be making he may be greater. He must broaden himself. He must know more of the scientific things pertaining not alone to his but as well to allied lines.

The strictly scientific has its place and a very important one in both the advancement of pure and applied science, and where can it be better worked out than in our educational institutions? In fact, the more research, the better, without neglect of the other duties of the instructor, is getting to be a well-recognized principle in the higher educational world. The main reason that more of this is not done is that an inadequate salary occasions the necessity of outside work in order to make both ends meet. Secondly, he is too lazy. Thirdly, he does not have the requisite brain power. When asked why he did not do more in his line I once heard the head of a department in a State university reply, "that it was all worked out and there was nothing more to do." The work for this type of man is digging post holes where there will always be plenty left to dig.

There is rarely found combined in a person the power of original thought, especially when it is logical, and the ability to take a given problem and carry through an investigation to its logical end, whether that end be positive or negative. Generally speaking, there is but one place where it is possible for men to get this training at the present time and this is in the graduate schools of our various educational institutions. It is very seldom that a man who has finished the ordinary four years of any one of our numerous scientific or technical courses in either a college or university has this faculty, at least to any degree.

This may be accounted for, to a certain extent at least, by the fact that the first thing which appeals to the student in engineering and most of the applied sciences is whether or not the particular subject in hand will be of any practical value, i. e., he is looking to his college education as a means to an end and that, in many cases, being the making of a living for himself and later for his family. Now, the courses, for the most part, were planned by men of vast experience who were able to see and know what were the subjects best suited for a man who wishes to prepare himself for a particular profession. Where it is equally possible to appeal to this practical instinct of the student, thus holding his interest in the work at hand without detriment to his training, the easier and further can he be made to progress in a given time.

A plan to bring about this sort of a thing in such a way that it would be possible for the student engaged in obtaining an engineering education to come in contact with and observe men who had obtained the training which he is striving for is by carrying on research of direct practical application. There should be a corps of instructors who are able not only to carry on industrial research themselves and to impart their knowledge to the student, but who can likewise interest men outside who are engaged in technical work to bring their problems to the university or technical school for solution. There they can either avail themselves of the facilities offered by the institution or establish a fellowship for their particular problem similar to those which have been established at the University of Kansas or the University of Pittsburgh.

There will be thus benefited—

(1) The student, who, kept at work by the constant force of inspiration, will learn by association to appreciate and strive to obtain the power of experimentally carrying on a logical line of thought to the desired end. (2) The instructor, who will come in contact with the practical application of scientific ideas, keep pace with the times and thus avoid fossilization. (3) The practical man, by including in his environment men possessed of a fund of scientific knowledge along lines in which he is quite likely to be rusty. Access to a library will do away with useless duplication and he will keep up to date along the line in which he is most interested.

University of Arizona,
Tucson. R. C. BENNER.

Presentation of the Perkin Medal to Dr. Charles Martin Hall.

At the meeting of the New York Section of the American Electrochemical Society, held in the Chemists Club in New York on Jan. 20, 1911, the Perkin medal was formally presented to Dr. Charles M. Hall.

The meeting was well attended, especially by members of the electrotechnical fraternity, who had come to honor Mr. Hall, many of them from outside of New York, Niagara Falls being, of course, well represented. A pretty touch of friendly sentiment and an international flavor were given to the proceedings by the presence and speech of Dr. Paul Héroult, of France.

The Perkin Medal.

The chairman, Dr. CHARLES F. MCKENNA, made the following introductory remarks which we give in abstract:

"The foundation of the Perkin medal was a happy act of scientific benevolence. Perkin's contemporaries in America, wishing to do something which would honor him in life and continue to keep his memory illustrious in science even after he should have passed away, chose to establish this medal and to see to it that in recurring years it should go as a reward to the ones who had struggled, striven and fought and forced nature to yield up further favors to men.

"Sir William Perkin has passed away and now after some further years in which we have witnessed the awarding of this honor we find the following result:

"Each year the achievement of Sir William himself stands out bolder on the pages of chemical history, each year the new award of this medal adds a link to the chain connecting the great work of industrial chemical advancement in America with the earliest and most pronounced advance made in England when aniline yielded up mauve. Each year the appreciation of the honor grows and the Perkin medal with its annual award is coming to be looked upon as the 'Concours' of chemical industry.

"And the thoughtful men who in founding this benevolence, drew up its guarantees and conditions, builded carefully and perhaps better than they knew. Besides leaving the selection of the recipient open to nomination by a large group of American societies interested in chemistry, they set no restriction as to the period in which the discovery may have been made. It is not necessary that the special work shall be that of the preceding year, or of any immediately preceding year. This leads to careful judgment and brings forward for the palm many a struggling chemist who in years past had known the disadvantages of inconspicuousness and the hardships of passing along the dusty road of conflicting interests.

"It happened that the importance of Sir William's own discovery was immediately grasped and that it traveled quickly throughout the world. But this is not always so in our chemical discoveries, and I think it can be said that the full appreciation of the significance of an American college student's experiments in electrolyzing a bath of alumina and kryolite was long in dawning.

"Therefore we must rejoice that the Perkin medal gives the chemical fraternity the opportunity to honor one of our confrères whose modesty has been as singular as his patience has been marked."

CHARLES M. HALL.

Dr. McKenna then introduced the doyen of the chemical profession in America, Dr. Charles F. Chandler, who made the formal presentation speech.

Address of Presentation.

Dr C. F. CHANDLER spoke in part as follows:

"It is my privilege and very pleasant duty as the senior past president of the Society of Chemical Industry to present to Charles Martin Hall, LL.D., the fifth impression of the Perkin medal in recognition of his most valuable work in applied chemistry.

"This work relates particularly to his discoveries and inventions in connection with aluminium. This is a subject which has interested me deeply from my student days. In 1854 I listened to Woehler's account of his discovery of aluminium in 1827, and the following year (1855) I was shown by Rose aluminium which he extracted from cryolite in the spring of that year. In 1869 I had the pleasure of making the acquaintance of Henri St. Claire Deville, who in 1854 and the following years prepared aluminium on a manufacturing scale. Later I had among my pupils at the School of Mines my warm friend Hamilton Y. Castner, who for two years monopolized the manufacture of aluminium by means of his cheap sodium, and finally for the past twenty years I have been very intimate with Dr. Hall, whose electrolytic process at Niagara Falls has produced the metal in such enormous quantities and at such a low price that it has monopolized our market and taken the place for innumerable purposes of other metals formerly employed.

"The name 'aluminium' is derived from alumen, which included alum, in which Margraf in 1754 recognized a peculiar earth which we call alumina and which was supposed a century ago to contain a metal. Sir Humphrey Davy, who in 1807 succeeded in extracting sodium from soda and potassium from potash, and a little later the metals of lime, magnesia, glucina and strontia, endeavored to reduce alumina by heating with the aid of 1000 galvanic plates an iron wire in contact with alumina in an atmosphere of hydrogen. The iron fused, became whiter, and on solution in acid yielded the earth alumina. He evidently produced an alloy of the metals. Nothing further was done till 1827, when Woehler reduced aluminium chloride with potassium and obtained aluminium as a gray, metallic powder, and later in 1845 by acting on aluminium chloride with potassium vapor obtained the metal in tin-white globules.

"In 1854 Henri St. Claire Deville became imbued with the idea of making aluminium a useful metal. He secured the interest of the Emperor Louis Napoleon, and with liberal grants of money was able to work on a factory scale. He employed aluminium chloride and sodium, introduced many improvements in processes for their preparation and application, and manufactured the metal in what for those days seemed very large quantities. Among other improvements he introduced cryolite as a flux. This mineral from Greenland was used experimentally to produce aluminium by the action of sodium in 1855 by both Rose and Percy. Deville's factories continued to produce aluminium on a moderate scale till about 1888, reaching a maximum output of over 5000 lb. per year along in the middle eighties. A few other manufacturers established works. The process of manufacture was, however, so expensive that aluminium was really a precious metal, used chiefly for fancy articles.

The price of metallic aluminium varied before 1890 as follows:

1855	$90	lb.
1856	27	"
1857	22.50	"
1862	12	"
1886	12	"

"In 1869 I purchased a little basket in Paris at the aluminum salesroom for $9. It weighed 4 oz.

"In 1886 Hamilton Y. Castner invented a new process for making sodium. He employed caustic soda in place of the carbonate and iron carbide in place of carbon as a reducing agent. As a result he reduced the cost of sodium from $1 per pound to 25 cents, a very important item, as it was never possible to make a pound of aluminium with less than 3 lb. of sodium. By June, 1888, his works at Oldbury, near Birmingham, were in working order, with a daily output of 250 lb., sold at $5 per pound. In 1889 the daily output was 500 lb. at $4 a pound.

"And then the manufacture of aluminium was discontinued because the new electrolytic manufacture from alumina produced the metal at $1 per pound.

"We now come to the achievements of Charles M. Hall, but before I go any further I wish to say that whatever praise I shall bestow on this great inventor I do not in the slightest degree disparage that other great inventor, Paul L. Y. Héroult, who worked on the same problem at the same time, across the Atlantic, made the same discovery independently and worked out an analogous process which has played the same important part in Europe that Hall's process has played in America.

"Charles Martin Hall was born in Ohio, Dec. 6, 1863, was educated in Oberlin and graduated there in June, 1885, when 21 years and 6 months of age.

"He studied chemistry while at school, became interested in the aluminium problem while in college and made many experiments in the hope of finding a more economical process for its production. Finally his thoughts turned to electrolysis, and about Oct. 1, 1885, he began to seek a suitable anhydrous solvent for alumina, operative at a practicable temperature, which would bring the alumina into a fluid condition in which it would yield to the electric current.

"Fluorspar and the fluorides of magnesium, sodium, potassium and aluminium were successively tried, but were found to be too infusible and to dissolve little, if any, alumina.

"On Feb. 10, 1886, he tried cryolite, the double fluoride of sodium and aluminium. This fused readily at a very moderate temperature and when he dropped in the white powder of alumina it dissolved and disappeared as does powdered sugar or salt in boiling water. It dissolved to the extent of more than 25 per cent and the solution was clear and limpid.

"He thus made his first great discovery. He proceeded at once to apply the electric current to this solution. His first experiments with clay crucibles were not successful; but on Feb. 23, 1886, he employed a carbon-lined crucible and was successful in obtaining aluminium. He had achieved success in inventing a process for making aluminium directly from alumina by electrolysis under conditions which promised to revolutionize the industry and furnish the metal at so low a price as to enable it to replace copper, tin, lead, zinc and other metals for an endless variety of purposes.

"Hall's age at this time was two months over 22 years and he had discovered and invented what had escaped Wochler, Rose, Deville and many of the other world-renowned chemists who had busied themselves with aluminium over a period of half a century.

"On July 9, 1886, Hall applied for his broad basic patent which was granted April 2, 1889, No. 400,766, with the following claims:

"'1. As an improvement in the art of manufacturing aluminium the herein-described process, which consists in dissolving alumina in a fused bath composed of the fluorides of aluminium and a metal more electro-positive than aluminium, and then passing an electric current through the fused mass substantially as set forth.

"'2. As an improvement in the art of manufacturing aluminium the herein described process, which consists in dissolving alumina in a fused bath composed of the fluorides of aluminium and sodium and then passing an electric current, by means of a carbonaceous anode, through the fused mass, substantially as set forth.

"'3. As an improvement in the art of manufacturing aluminium, the herein described process, which consists in dissolving alumina in a fused bath composed of the fluorides of aluminium, sodium and lithium, and then passing an electric current, by means of a carbonaceous anode, through the fused mass, substantially as set forth.'

"He also received four additional patents for modifications of his original process. Hall did not escape the usual experience of the successful inventor. He was obliged to defend in court the originality of his invention. The suit was brought in the United States Circuit Court of the Northern District of Ohio and after an exhaustive discussion of the prior art the patent was sustained. The opinion was written by Judge William Howard Taft, now the President of the United States. He wrote: 'Hall was a pioneer and is entitled to the advantages which that fact gives him in the patent laws.'

"The court declared the patent valid and issued a perpetual injunction against the defendants. For various reasons there was considerable delay in devising suitable means for applying the invention on a manufacturing scale and securing the necessary capital. But at last, in November, 1888, he began work in his factory at Kensington, near Pittsburgh, producing 50 lb. of metal a day. Since that date his progress has been wonderful. He soon erected larger works at Niagara Falls as the first consumer of the electricity supplied by the Niagara Falls Power Company. At the present time the company has three establishments at Niagara Falls, one at Massena in New York on the St. Lawrence and one at Shawinigan Falls in Canada. The total consumption of electricity is 140,000 hp, probably a larger amount than is consumed by any other electrochemical works in the world. The annual output of aluminium is now 40,000,000 lb. The first metal produced at Kensington was sold at $2 per pound; the price now is about 22 cents.

"The early dreams of the young undergraduate have certainly been realized.

"Hall has made many other inventions, several of which have been patented. Six of these are for improved methods for preparing pure alumina, one of which is still employed for preparing this material for use in the works. He has also patented improved methods for making improved carbon anodes for use in the works. There are very many other matters in connection with Hall's work to which I should be glad to call your attention did time permit. I think, however, that I have laid before you a most creditable record of discovery to satisfy you that your committee has been wise and just in awarding to Dr. Hall the gold medal which was established to honor forever the memory of the great chemist, Sir William Henry Perkin, and by association with him to honor our own most distinguished fellow chemists.

"Dr. Hall's achievements certainly entitle him to a place in the front rank of electrochemists and his youthful successes must ever prove an encouragement to other young men who develop a love for this branch of applied science. Personally Dr. Hall is a man of the greatest modesty and lovable character."

In turning to Dr. Hall, Dr. Chandler concluded: "Charles Martin Hall, Doctor of Laws, my dear friend, it gives me the greatest pleasure as the representative of the affiliated chemical and electrochemical societies to place in your hands this beautiful token of appreciation and affection of your fellow chemists."

Personal Reminiscences of Dr. Hall.

Dr. Charles M. Hall expressed in a few graceful sentences his thanks for the medal. "I am glad to have this medal on

account of what it represents and on account of the manner in which it has been awarded, and I shall treasure it among my most valued possessions."

Dr. Hall then gave an account of some personal and unpublished facts in connection with his work on aluminium.

"My first knowledge of chemistry was gained as a school boy at Oberlin, Ohio, from reading a book on chemistry which my father studied in college in the forties. I still have the book, published in 1841. It is minus the cover and the title page, so I do not know the author. It may be interesting now to see what this book, published 70 years ago, says about aluminium. It states: 'The metal may be obtained by heating chloride of aluminium with potassium in a covered platinum or porcelain crucible and dissolving out the salt with water. As thus prepared it is a gray powder similar to platinum, but when rubbed in a mortar exhibits distinctly metallic luster. Fuses at a higher temperature than cast iron and in this state is a conductor of electricity but a non-conductor when cold.'

"Later I read about DeVille's work in France and found the statement that every clay bank was a mine of aluminium and that the metal was as costly as silver. I soon after this began to think of processes for making aluminium cheaply. I remember that my first experiment was to try to reduce aluminium from clay by means of carbon at a high temperature. I made a mixture of clay with carbon and ignited it in a mixture of charcoal with chlorate of potassium. It is needless to say that no aluminium was produced. I then thought of cheapening the chloride of aluminium then used as the basis for aluminium manufacture and tried to make it by heating chloride of calcium and also magnesium chloride with clay, following the analogy by which iron chloride is produced when common salt is thrown into a porcelain kiln. A little later I worked with pure alumina and tried to find some catalytic agent which would make it possible to reduce alumina with carbon at a high temperature. I tried mixtures of alumina and carbon with barium salts, and also the same mixture with cryolite and carbonate of soda, hoping to get a double reaction by which the final result would be aluminium. I remember buying some metallic sodium and trying to reduce cryolite, but obtained very poor results. I made some aluminium sulphide, but found it very unpromising as a source of aluminium then as it has been ever since.

"On a later occasion I tried to electrolyze a solution of aluminium salt in water, but found nothing but a deposit of alumina on the negative electrode. I did not give a great deal of time to these experiments, as I was a student in college at the time and worked on three or four other attempted inventions. I had studied something of thermochemistry and gradually the idea formed itself in my mind that if I could get a solution of alumina in something which contained no water and in which the solvent was chemically more stable than the alumina, that this would probably give a bath from which aluminium could be easily obtained by electrolysis. The idea remained in my mind and in February, 1886, I began to experiment on this plan. The first thing in which I tried to dissolve alumina for electrolysis was fluorspar, but I found that its fusing point was so high as to be rather discouraging. I next made some magnesium fluoride, but found this also to have a rather high fusing point. I then took some cryolite and found that it melted easily and melted dissolved alumina in large proportion. Then I rigged up a little electric battery—mostly borrowed from my professor of chemistry, Professor Jewett, at Oberlin College, where I had graduated the previous summer of 1885. I melted some cryolite in a clay crucible and dissolved some alumina in it and passed an electric current through it for about two hours by means of carbon electrodes. When I poured out the melted mass I found no aluminium. It then occurred to me that the operation was interfered with by impurities, principally silica dissolved from the clay crucible, so I next made a carbon crucible, inclosed it in a clay crucible and repeated this experiment. This time, after passing the current for a couple of hours, I poured out the material and found a number of small globules of aluminium. I was then quite sure that I had discovered the process that I was after.

"I then undertook to broaden and improve the process and found that I could use, instead of cryolite, other double fluorides, particularly a double fluoride of potassium and aluminium. The most important change, however, which I made at this time was in the material used as an anode. I wanted to get rid of the burning up of the carbon anodes. I tried a platinum anode and found that it seemed to work all right, but it was too expensive. Then I discovered that if I used a fusible bath of a potassium double fluoride with a sodium double fluoride I could use a copper anode, which immediately became coated with a thin film of copper oxide and acted like a permanent platinum anode. This was not a step in advance as I thought it was, as more or less copper gets into the reduced aluminium and the use of a copper anode led me to use very fusible baths which on the whole do not work as well as the less fusible baths. It is probable that this change delayed a successful result for a year or two.

"When worked on a small scale this process with any of the baths I have mentioned, and with either copper or carbon anodes, is not apparently promising. The ampere-hour efficiency is low, sometimes zero, and the bath, whether composed of sodium or potassium salt, becomes filled with a black substance which accumulates and renders the process very difficult. I presume that my friend, Dr. Héroult, whom I have the pleasure of seeing here to-night, who invented the process independently in France about the same time as I did, encountered the same difficulties I did. In spite of the difficulties mentioned, however, I had great faith in the theoretical possibilities of the process and believed that the practical difficulties could be overcome, so I stuck to it from the start.

"On the financial side I had in the course of three years three different sets of partners or backers, of whom two sets became discouraged and gave up. In the summer and fall of 1886 I worked with some people in Boston with whom my brother had made some financial arrangement. The results there obtained were not satisfactory to them and in October, 1886, my Boston friends declined to go further and I returned to my home in Oberlin, Ohio. In December, 1886, I found that a bath composed of a very fusible double fluoride of aluminium and potassium, with copper anodes, worked much better than anything I had before tried. I have here a number of buttons of aluminium made by this method at this time. The larger one was made with current from a galvanic battery on Dec. 7, 1886, and weighs about eight grams. After this I negotiated with the head of one of the large chemical manufacturing companies of the United States with headquarters at Cleveland, but we could not finally agree. I thought then, and have thought since, that this gentleman was the kind of man whom the proverbial inventor meets when he is deprived of the fruits of his labor. He was extremely careful and conservative and was always wanting to take a few days more to think the matter over. He kept me on the string six months and the kind of contract which he finally offered seemed to me too entirely one-sided. The gentleman told a friend of mine afterward that I was no business man, which was no doubt true, but I received what seemed to me much fairer treatment from all with whom I afterward had business dealings and found much more liberal associates and friends.

"The Cowles Electric Smelting & Aluminium Company, who were then making aluminium alloys at Lockport, N. Y., were the second set of people who became interested in my invention. They took an option on it and I spent a year with them, from July, 1887, to July, 1888. They finally threw up their option. The baths which I used at Lockport, at first, worked well for a few days, but after a time they would become less efficient. I finally worked out a system by which the difficulties were overcome. This was by making a bath consisting partly of calcium fluoride or fluorspar and adding 3 per cent or 4 per cent of calcium chloride and using carbon anodes. I reasoned that

chlorine was evolved and burned up the objectionable compound which spoiled the bath. After finally overcoming the difficulties which I have mentioned I made several pounds of aluminium in small crucibles which I showed to Mr. Alfred Cowles and gave him all the facts in relation to the same, but he was not interested.

"I then sent a representative—Mr. Romaine Cole, now dead—to Pittsburgh, who got together the gentlemen who formed the Pittsburg Reduction Company, now the Aluminium Company of America, and we immediately started in the summer of 1888 to build and operate a commercial plant on Smallman Street in Pittsburgh. We had at our disposal about 50 hp in electrical current of 2000 amp. It took a few weeks after starting to get the dimensions of our baths and so forth just right, and then the difficulties which I have referred to disappeared as if by magic. The clogging and spoiling of the bath, which had caused trouble for the last three years, did not occur on a large scale. No calcium chloride was required. It seems that this is a process, unlike a good many others, which works badly on a small scale and well on a large scale. I accounted for this by the fact that on a large scale the electrodes are further separated and there is less circulation between the positive and negative electrodes, which lowers the efficiency and favors the formation of the clogging black compound.

"We also found, as I had predicted nearly three years before and stated in a patent application filed two years before, that on a commercial scale no external heat was required to keep our baths in fusion. This was a great advantage, but I believe that it resulted from a law of nature and not from any invention at the time, as we did not use any excess of current for maintaining fusion, but only the normal current and voltage for electrolytic purposes, and the use of the electric current for fusing and heating in connection with electrolysis was a thing which had been disclosed and published almost a century before.

"The business of manufacturing aluminium has now grown to a great commercial business. Many workers have contributed to it and the credit is to be divided among many. Our financial people, particularly the gentlemen of the Mellon Bank of Pittsburgh, have given indispensable aid in purchasing our stock and in loaning us money most generously. Our patent attorneys and experts, our engineering and chemical staff, sales agents, superintendents, foremen and others have all done their share."

"In the commercial development of the business," Dr. Hall concluded, "the greatest credit is due to the late Captain Alfred E. Hunt and to Mr. Arthur V. Davis."

Personal Reminiscenes of Dr. Héroult.

Dr. Paul Héroult then made the following address:

"There is a verse of Kipling which reads as follows:

> "'Ship me somewhere east of Suez,
> Where the best is like the worst;
> And there ain't no ten commandments,
> And a man can raise a thirst.'

"I was in that particular mood when I made my first acquaintance with aluminium in large quantities. At the time I had a friend who since then became my partner, but for the time being we were both dead broke. We had pawned everything in sight and also other things which were not in sight.

"Finally my partner had a bright idea. He brought back from home a stick of aluminium about 6 in. long which was valued very high in his family as a personal souvenir of Saint Claire Deville.

"As we handed it to the pawnbroker, the latter said: 'What is that, bar silver?' We said: 'Better than that; that is aluminium.' 'Aluminium,' he said, 'what is that?'

"He weighed it in his hand and said: 'Why, is this hollow?' We said: 'No, that is aluminium and it is worth 120 francs per kilo.' After some thought he said: 'Well, I will give you 2 francs for it,' say 40 cents in American money.

"On a hot summer's day it was better than nothing, and we took the money with the firm intention of buying the stick back, which we never did. Maybe that was one of the reasons why, later on, I had to make good and replace it.

"No material change took place in the industry of aluminium for three years after that event, but the actual fact of the development of said industry was preceded by rumors to the effect that something new was coming.

"I can remember there was a shop on the Grand Boulevard in Paris where there was a display of aluminium goods, mostly thimbles, if I remember rightly; besides wedding rings, brooches, statuettes, a few coils of wire and quite some interesting specimens of aluminium bronze in the form of coffee pots, sugar bowls, etc.; none of the cheap stuff which is sold nowadays. I bought once a thimble for my mother out of my savings. I was a good boy in those days. Every one of those articles had on the Paris finish and sold like silverware.

"In the nineties this same shop practised the same prices, although the cost for ingots had come as low as 25 francs per kilo.

"This was a wonderful time for the aluminium makers; they were making money hand over fist, at least on the books. There was no use for any syndicate at that time. Aluminium was being piled up in the store and the stock of finished product reckoned at above-named price. But this did not last long; customers were scarce and finally the bankers got tired of lending money to people who piled up stock; it became necessary to sell.

"Another price was established at 8 francs per kilo which did not prove successful either. Then came the 5 marks which originated with the Swiss Company; finally it seemed to open the bunghole of the cask.

"Now after various vicissitudes the price in the old country looks pretty near settled around 20 cents per pound and will vary probably according to the price of copper.

"Twenty-five years ago the aluminium industry employed about 10 men; the production was 1½ tons a year, the total value of which was $30,000. Nowadays the same industry produces 50,000 tons at a value of $20,000,000 and employs from 15,000 to 20,000 men.

"If we take the average consumption of copper at 900,000 tons a year at a value of 13 cents per pound, the total value of ingot metal will be $234,000,000 a year comparing with the $20,000,000 for aluminium, say one-tenth. But 13 cents is pretty near the rock bottom price for copper. At 20 cents per pound aluminium presents a great advantage for most uses.

"Aluminium is slowly wedging its way in the metal market. It looks probable that in a course of 10 or 15 years the consumption of the new metal will be equal to that of copper and that after the golden age, the stone age, the bronze age and the iron age we will have the aluminium age.

"My friend Hall and myself have been fighting for 15 years, most of the shots going wild on account of the long reach over the Atlantic.

"Since we met, however, we conceived a better opinion of each other and I take great pleasure to-night in extending to my friend Hall my sincere congratulations on the award to him of the Perkin medal."

Concluding Speeches.

Dr. Jos. W. Richards then gave some reminiscences of his friendship of many years with Dr. Hall. He emphasized that Hall had taken at Oberlin College the classical, not the scientific, course. It seems as though a broad foundation such as given by a classical course is a very suitable basis for later technical work.

Dr. Richards then gave a brief review of the various uses of aluminium. First, in the steel industry as a deoxidizer. Second, as an electric conductor. Third, in the reduction of refractory oxides to carbon-free metals and in welding by the aluminothermic method of Dr. Hans Goldschmidt. Fourth, for culinary utensils aluminium seems to be the ideal material; it is practically indestructible and its use for this purpose should very largely increase. Dr. Richards also referred briefly to

the use of aluminium in the chemical industries, to the use of stiffened aluminium for automobile and airship construction, to the use of aluminium bronze, etc. There was quite an interesting collection of various aluminium products on exhibition.

Dr. Richards concluded that the invention of aluminium ranked with the invention of the Bessemer steel process as the most important technical achievement of the nineteenth century.

In a few graceful words congratulations were expressed to Dr. Hall by Dr. Wm. H. Walker for the American Electrochemical Society and by Dr. Chas. Baskerville for the American Chemical Society.

After the formal meeting was over there was an informal session of the Verein Deutscher Chemiker.

Nitric Acid and Nitrates from Air.

At the recent Königsberg meeting of German Naturforscher und Aerzte, Dr. J. ZENNECK gave an interesting outline of the different processes for the fixation of atmospheric nitrogen by electric discharges through air. The paper is printed in full in *Phys. Zeit.*, Oct. 15, 1910. (See also p. 99 of this issue.)

Fig. 1 shows the arrangement of the principal apparatus for demonstration purposes. The air first enters a blower (in practice a powerful turbo-compressor is used which supplies some 20,000 cu. m of air per hour to the plant).

The air then enters the "furnace" in which a small portion

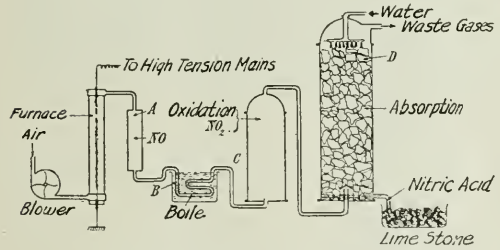

FIG. 1—APPARATUS FOR DEMONSTRATING THE MANUFACTURE OF CALCIUM NITRATE FROM ATMOSPHERIC NITROGEN.

of the nitrogen and oxygen combine to NO. The colorless gas passes off through the glass tube *A* into the boiler *B*, where the heat in the gas is utilized. In the model for demonstration purposes it is simply a water tank with copper tubes. In practice the apparatus has the same form as any large boiler. The steam produced in it is utilized for heating and evaporating.

After the gas has cooled off it has an opportunity of rest in a large vessel, the "oxidation chamber," in which the NO combines with free oxygen in the air to form NO_2.

The gas then enters a glass cylinder *D* filled with coke particles, through which water runs down, absorbing the NO_2 and forming nitric acid. In practice the nitric acid formation is carried out in very large towers.

The formed nitric acid is finally passed off into a receptacle filled with limestone for the formation of calcium nitrate.

The essential difference of the different commercial processes is to be found in details of the furnace construction. But in all cases it is an arc furnace. Convenient electrode holders for high-tension and arc experiments are shown in Fig. 2, *a* and *b*.

To get as much air as possible in contact with the arc the Pauling Brothers employ an arrangement similar to the horn lightning arrester, Fig. 3. (Details of the Pauling process, as carried out in a commercial plant at Innsbruck, Tyrol, were given in our October issue, 1909, Vol. VII, page 430.)*

Birkeland and Eyde deflect the arc, which is produced between two horizontal electrodes by magnetic means so as to form a flaming disk. The form of their furnaces is shown in Fig. 4. (See also our Vol. II, page 399; Vol. IV, pages 126, 295 and 360; Vol. VII, p. 304 and 305; Vol. VIII, p. 451.)

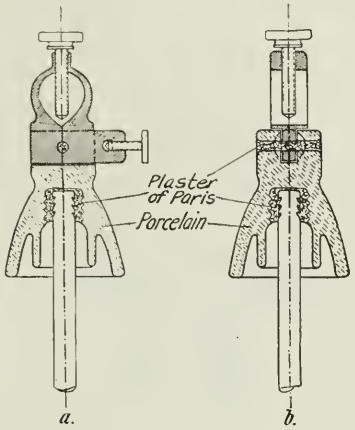

FIG. 2—ELECTRODE HOLDERS.

Petersson, Brion, and Moscicki employ a similar principle. One electrode is in form of a rod, the other is a coaxial cylinder. In the annular space between the two the arc is playing and is caused to run around continually by means of a magnetic field, the lines of flux of which have approximately the direction of the axle of the two electrodes. This is shown in Fig. 5. (See also our Vol. V, page 492.) The furnace of Moscicki

FIG. 3—PRINCIPLE OF PAULING APPARATUS.

has been further developed in conjunction with the Aluminium Industrie Gesellschaft in Neuhausen.

The furnace of the Badische Company is shown in Fig. 6. The long arc plays in the central tube and the air passes around it in a spiral path from the bottom of the tube to the top. (For further details see our Vol. VII, page 245.)

*In connection with this and the following processes the article by Lamy and Lamb on page 99 should be compared.—EDITOR.

This arc is interesting in various respects from the standpoint of the physicists. While long arcs are usually very unstable the arc is in this case maintained in a very quiet state by means of the spiral air current encircling it. Further, it is unusually long, for instance 8 m (26 ft.) at an effective tension of not over 4000 volts. Further, the conditions of pressure

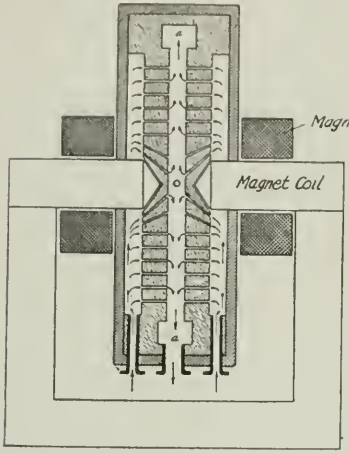

FIG. 4—BIRKELAND-EYDE FURNACE.

and temperature in such an air vortex are peculiar; in the axle of the vortex the pressure is well below atmospheric pressure. Such an air vortex acts somewhat like a centrifuge, the heavier and colder air being pressed to the outside against the walls of the tube. In consequence of this the exceedingly hot internal core with the arc is surrounded by a layer of relatively cold air.

This fact explains why Dr. Zenneck could carry out his experiment in a glass tube, although more than 10 hp were used

FIG. 5.—PICTURE OF MOSCICKI ARC.

so that considerable heat was developed. For the same reason comparatively narrow tubes can be used in the commercial furnaces with their enormous temperatures, and these tubes can be made of iron without being destroyed by the heat.

Further, the success of this type of furnace seems to contradict the hypothesis that the formation of the nitrogen oxide by the arc is a purely thermal phenomenon. According to this hypothesis it is not only necessary to heat the air to an exceedingly high temperature, but also to chill it as suddenly as possible. This latter condition is not very well fulfilled in this type of furnace.

The air to be treated is preheated by the gases leaving the furnace. The path of the air through the furnace is clearly shown in Fig. 6.

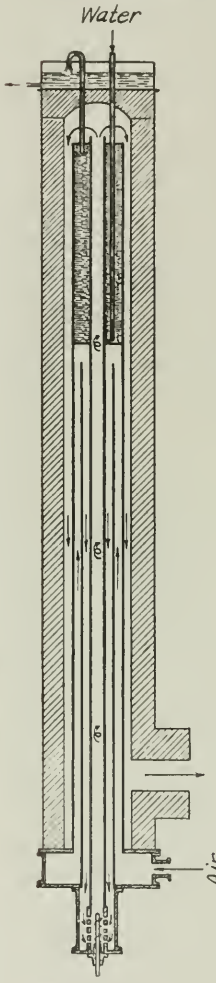

FIG. 6—FURNACE OF BADISCHE COMPANY.

The method of starting the arc is very simple. Through a little hole in the bottom a little rod of wood is introduced wound with wire so as to produce a conducting contact between the lower electrode and the wall of the tube. An arc is formed which is quickly carried upward by means of the air vortex until it is in its normal central position between the lower and upper electrodes.

Dr. Zenneck gave finally a brief outline of the electrical engineering features of the plant of the Badische Company. In the hydroelectric power plant the three phases of the large three-phase alternators are connected to the three transmission cables. A fourth thinner cable connects the neutral point of the alternator with the earth in the furnace house.

The three main transmission cables are connected each to one electrode of one furnace, the other electrode being earthed. But in each of the three main cables a large inductance coil is inserted in series with the arc. This is absolutely necessary, since without the inductance coils there would be danger of the arc being extinguished or the machine burning out. The size of these inductance coils is many times larger than ordinary inductance coils as usually employed.

These inductance coils fulfil the same purpose as a series resistor, but they represent a reactance instead of resistance—that is, they consume very little energy, since the phase difference between e.m.f. and current is very nearly 90 deg.

A novel engineering feature of the installation is the direct use of high-tension currents in the plant. The high-tension currents enter directly the works and right at the furnace electrode there is a tension of several thousand volts. This involves great danger and has necessitated special precautions.

Although the arcs are very quiet and steady once in a while an arc may be extinguished and a load of at least 1000 hp is thus suddenly taken from the generator. In the same way when the arcs are started the generators are suddenly loaded. Starting appliances, such as are used with motors, can be employed only to a small extent and are used only with very large furnaces: several inductance coils are connected in parallel and one is switched in after the other.

Further, the current and voltage conditions in the furnaces are very different from usual electrical engineering practice and great precautions must be taken in the measurements to get exact results. This becomes evident when it is found that two precision instruments, which were both calibrated by the Reichsanstalt and which agree absolutely with each other under ordinary conditions, gave readings different by 4 per cent. Commercial instruments, which are ordinarily exact by 1 per cent or 2 per cent, were found to give readings which were wrong by 12 per cent or more.

Even the connections of the instruments to the line conductor involve difficulties, as the line conductor carries a current of 200 to 300 amp and is at some thousand volts against earth.

Dr. Zenneck emphasizes these difficulties because the fundamentally important determination of the furnace efficiency depends on an exact measurement of the electrical energy. He concludes: "Since the measuring methods mostly employed in engineering fail certainly in this case, all statements in the literature on the efficiency of the different furnace systems

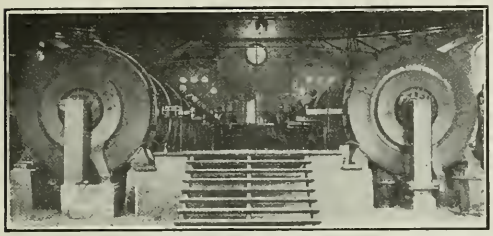

FIG. 7—FURNACE HOUSE, NOTODDEN.

should be regarded with unlimited skepticism if the statements do not prove clearly that the measurement of the electrical energy was exact."

* * *

One special difficulty of the measuring methods is discussed by Dr. J. ZENNECK in an article in *Physikalische Zeitschrift*, Oct. 15. In ordinary engineering practice measuring transformers are widely used, the measuring instruments being connected to the low-voltage terminals. But in connection with long arcs as used in the furnace of the Badische Company the employment of measuring transformers may involve unduly large errors. Dr. Zenneck claims that to be sure of the result it is necessary to insert the current coil of the electrodynamic wattmeter directly into the line conductor and to connect the voltage coil in series with non-inductive resistors across the line.

But this involves the difficulty that as the instrument is charged to a high voltage purely electric (electrostatic) forces are acting on the movable system of the instrument. Errors due to this fact must be eliminated. In the article referred to a simple method is described how to calibrate the instrument so as to eliminate this error once for all.

* * *

The works for the production of calcium nitrate from atmospheric nitrogen at Notodden, Norway, using the Birkeland and Eyde process, and especially the electric power plant, are the subject of an article in *Teknisk Ugeblad*, reproduced in London *Electrical Review*, Dec. 30. The power plant contains four alternators, generating three-phase currents at 10,000 volts, 600 amp per phase, the frequency being 50 cycles per second. All four generators work in parallel on a system of busbars, which are connected with Notodden by three cables. The current is transformed by oil-cooled transformers and then supplied to the furnace, inductance coils being arranged in series.

The furnace house (Fig. 7) is a building with a floor area of about 21,500 sq. ft., constructed entirely of brick and iron. The number of furnaces is 36. "The diameter varies from 6 ft. to 8 ft., but the length is comparatively small. The electrodes are placed in the center of the furnace, diametrically opposite each other, and between them the electric arc is formed. The air is conveyed to the interior of the furnace through the walls of the chamber, which is made of firebricks, and from this chamber the nitrous gases pass through a fireproof channel. The temperature of the chamber is generally about 3500° C., while that of the escaping gases varies from 800° C. to 1000° C. The furnace can be kept going for weeks without interruption; the brickwork lasts from four to six months, while the electrodes have to be charged every three or four weeks.

"The necessary supply of air is obtained by means of centrifugal fans. The gases from the furnaces are collected and conveyed through two large pipes, each with a diameter of 6 ft., to the boiler house, where the heat contained in them is utilized for various purposes.

"From the furnace house the gases pass to a cooling house through large pipes of aluminium, placed in flowing water, and having been sufficiently cooled pass on to vertical iron cylinders, lined with acid-proof stone, where the oxidation takes place."

The information given concerning the absorption of the oxide vapors and production of calcium nitrate is meager. The production at Notodden during the first year amounted to 20,000 tons of nitrate of lime, but when all the projected works have been completed the minimum production will be 100,000 tons per year. The total capital invested when the new buildings and extensions are completed will be about $17,500,000.

Concentration of Platiniferous Copper Ore at the Rambler Mine, Wyoming.

Editorial Correspondence.

Historical.

In the winter of 1901 it was discovered that platinum occurred in the copper ore of the Rambler mine, located in Albany County, Wyoming, about 50 miles southwest of Laramie. The occurrence was first suspected from the difficulty experienced in making satisfactory assays for gold on shipments to the Denver smelters. In the usual gold assay platinum would be collected in the final cupellation, and it is difficult to see how it could have escaped detection for so long a time, for up to the date of actual discovery in 1901 nearly 4000 tons of 25 to 30 per cent copper ore had been shipped from the mine. Of this quantity, about 2500 tons had been shipped to the smelter at Encampment, Wyoming, and smaller tonnages to other plants. The incident is more striking in view of the fact the Rambler Company had never received pay for gold in its ore, as it was presumed that this metal occurred in quantities smaller than was paid for in ordinary smelting practice.

The first tests to prove the discovery were made in the laboratory of Henry E. Wood, Denver, and published by Prof. Wilbur C. Knight, of the University of Wyoming.[1] These tests showed that various copper minerals from the mine carried from 0.10 oz. to 0.70 oz. platinum per ton, while several carloads of covellite ore carried from 0.40 oz. to 1.40 oz. platinum per ton. About the same time Wells and Penfield[2] determined the mode of occurrence of the platinum to be sperrylite, $PtAs_2$. Their work was done on a sample of covellite, from an ounce of which they recovered six brilliant crystals of sperrylite.

Subsequent to this time many confirmatory tests were made by members of the company's staff, the United States Geological Survey, and others. The later investigations gave evidence of the presence, in considerable quantities, of other members of the platinum group of metals. The first commercial results were obtained from consignments of high-grade copper ore to the Chicago Copper Refining Company, Blue Island, Ill. On the assumption that all of the noble metals ultimately would be collected in the copper base in the smelting process, and later precipitated as anode slime in the electrolytic refining process,

[1] *Eng. & Min. Journ.*, Dec. 28, 1901.
[2] *Amer. Journ. Sci.*, Feb. 1902.

arrangements were made to recover this slime for further treatment. Assays of this slime showed the presence of considerable quantities of platinum and palladium, the values ranging from $5.50 to $6.50 per pound. One lot assayed 226 oz. platinum and 166 oz. palladium per ton of slime. From two portions there were actually recovered 16.74 oz. of platinum, 37.5 oz. of palladium, 5.33 oz. of gold and 38.55 oz. of silver.

Investigation of Treatment Methods.

The definite and rather extensive occurrence of the metals of the platinum group having been established, the company was confronted with the problem of ore treatment. It was apparent that much had been lost in the several thousand tons of ore shipped to copper reduction works, and that some system must be devised for saving the precious metals. A small matting furnace which had been erected at the mine had not been operated successfully, as the present appearance of the old slag dump, copper bottoms and matte shells now indicate. The failure of this plant is not surprising in view of the abundance of decomposed diorite, or so-called talc, in some of the ore, carrying 55 per cent silica and 30 per cent alumina and iron. Some of the highest grade platinum ore is especially refractory in the smelting process, one analysis showing 12.75 per cent insoluble and 52.85 per cent alumina and iron, with no lime and magnesia.

The complexity of the problem of suitable ore treatment will be better understood from a consideration of the variety of copper minerals existing in the mine, much of it low grade and requiring concentration. The Rambler has yielded, up to date, the following copper minerals:

TABLE OF MINERALS OCCURRING IN THE RAMBLER MINE.[3]

Mineral.	Composition.	Sp. Gr.
Sulphides		
Chalcocite	Cu_2S	5.7
Chalcopyrite	$(Cu_2)S_2(Fe_2)S_3$	4.2
Covellite	CuS	4.0
Carbonates		
Azurite	$(CuOH)_2Cu(CO_3)_2$	3.7
Malachite	$(CuOH)_2CO_3$	3.8
Oxides		
Tenorite	CuO	5.8
Cuprite	Cu_2O	6.0
Chalcotrychite	Cu_2O	6.0
Chloride		
Atacamite	$Cu(OH)_2Cu(OH)Cl$	4.1
Sulphate		
Chalcanthite	$CuSO_4\ 5H_2O$	2.2
Silicate		
Chrysocolla	$CuSiO_3 . 2H_2O$	2.1
Native Copper		
	Cu	8.9

These minerals occur also in diorite in all stages of alteration, even the socalled talc carrying copper and precious metals. One of the minerals, chalcanthite, is soluble in water, and the carbonates and oxides do not yield readily to concentration. Furthermore, all of these copper ores occur closely associated, one mineral sometimes coating another, and it would be almost impossible to sort them. Finally, all of them, but particularly the covellite, carry the precious metals of the platinum group very finely divided, the largest crystals of sperrylite isolated by Wells and Penfield measuring only 0.12 m in diameter. Sperrylite has a specific gravity of 10.6 and the metals of the platinum group have specific gravities ranging from 16 to 21.

The following table[4] shows the distribution of precious metals in the ores:

Identification of Sample.	Value per ton in Precious metals.	Copper.
High-grade platinum, circular drift	$36	$3.28
Hard talc, N. W. drift	12	2.75
Sulphide, black drift	26	1.45
Talc, black drift	20	5.88
Talc, covellite drift	32	12.34
Black material, black drift	88	4.65
High-grade platinum, opposite talc contact	100	75.00
White talc at contact, first level	26	5.75
Covellite, covellite drift	80	59.00
Brown talc at contact, first level	12	4.90
Precipitate above talc, covellite drift	116	68.60
General sample, stope level	26	16.40
Low grade, second level	12	2.00

From these considerations it will be seen that the Rambler ores offered a most interesting problem in metallurgy.

As a result of experiments made in 1906 under the direction of Dr. David T. Day, of the United States Geological Survey, it was found that when the ore was crushed to 2 mm and concentrated on a Wilfley table about one-half the platinum content of the ore was recovered in the concentrate, the other half being lost in the middling and tailings. The test further indicated that the precious metals occurred very finely divided and it was Mr. Day's opinion that grinding to ½ mm would result in a saving of 80 to 90 per cent of the precious metals.

In the spring of 1909 concentration experiments were carried out at the ore testing works of H. E. Wood, Denver. The results obtained on ore crushed to 20-mesh were comparable with those obtained by Mr. Day. About 56 per cent of the precious metals were obtained in a concentrate assaying 1.70 oz. platinum per ton. On reconcentrating this concentrate it was possible to obtain a precious metal product carrying 13.06 oz. platinum per ton, the ratio of concentration being 150 of crude ore assaying 0.69 oz. platinum per ton into 1 of precious metal concentrate assaying as stated above. A second test on material ground to pass a 16-mesh screen gave a concentrate assaying 1.38 oz. platinum per ton, which on reconcentration yielded a product assaying 14.62 oz. platinum per ton. This final product represented a concentration of 191 tons of crude ore into one of precious metal concentrate.

Later tests conducted by Prof. A. C. Dart, of the School of Mines, University of Wyoming; Mr. Robert A. Marr, consulting metallurgist, Union, Ore., and FitzGerald & Bennie, electrometallurgists, Niagara Falls, N. Y., indicated the possibility of profitably concentrating the low-grade copper ore by grinding fine enough to liberate the precious metals, making a high-grade precious metal concentrate and a copper concentrate carrying some precious metals. Following these opinions the company has erected a concentrating mill at the mine.

Rambler Experimental Mill.

The mill was erected adjoining the old ore bins, so that the ore could be handled from them by gravity. The mill equipment consists of crusher, rolls, trommels, classifier, Wilfley tables and canvas tables. As the plant is being operated in an experimental way, the system of treatment cannot be said to be definitely settled. In fact, the mill has been in operation just long enough to present a number of problems that have not been solved as yet, and it is expected that experimental operation will continue for some time. It will be necessary to determine what commercial products can be made most economically and in what quantity they can be produced. it will then be possible to negotiate the sale of the concentrates or consider their treatment locally, although the latter is improbable.

The mill was designed and erected by Mr. R. A. Marr, but its present operation is under the direction of Mr. Dart, who is acting as consulting engineer to the company. On page 77 is a diagram of the flow of ore through the mill.[5]

The crusher is set to crush to ½ in., and the rolls to grind to 20-mesh. The trommels are fitted with punching screens to deliver 20-mesh material. Three Wilfley tables are fed from

[3] Composition and specific gravity taken from Frazer & Brown Tables for the Determination of Minerals, 6th Edition.

[4] Assays by Fitz Gerald & Bennie. Precious metals calculated at $20 per ounce and copper at 14 cts. per pound.

[5] The abbreviation P.M. used in the diagram and following tables indicates "precious metals."

the three compartments of the classifier, and the overflow from the last compartment runs to two canvas tables. At present three products are being taken off the tables, viz., a high-grade precious metal concentrate comprising a streak of about 1 in. wide at the top of the table; a copper concentrate, and a combined middling and tailing, the last being impounded for further treatment. Owing to the lack of a regrinding machine the middling is being combined with the tailing for the present, although conditions indicate the advisability of regrinding the middling. The precious metal streak is made up of very finely divided particles, and carries the major percentage of the platinum group metals in the ore; the copper concentrate carries the bulk of the sulphides, and the middling is composed largely of 20-mesh grains of the carbonate copper ores.

The following table gives the assays of the various table

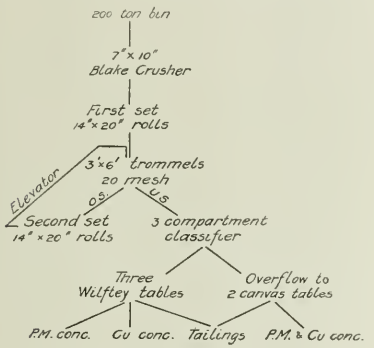

DIAGRAM OF FLOW OF ORE THROUGH MILL.

products, as made June 25, 1910, by Mr. L. S. Worthington, the company's chemist and assayer. The methods of assay will be discussed later.

	Ounces per Ton.					Per cent
Description.	Total P. M.	Au.	Pt.	Ag and Pd.	Ir.	Cu.
Mill feed	1.27	....	.....	....	....	2.8

Cu Conc. table No. 2.....	2.40	Trace	0.14	1.76	Trace	.....	12.6
P. M. Conc. table No. 3..	72.50	6.92	7.28	11.22	13.00	34.08	23.4
General P. M. Conc. tables Nos. 1 and 2.....	15.28	2.64	5.78	5.86	0.38	0.62	18.4

An imperfection in table No. 3 made it necessary to take the sample of precious metal concentrate periodically by hand. When the sample was not being taken the precious metals ultimately combined with the copper concentrates and were, therefore, not included in sample six of the above table. For the same reason no assay appears for the copper concentrate of table No. 3. In preparing the samples for assay no metallics were observed on a 100-mesh screen. Of the precious metal concentrates 33 per cent of the sample from table No. 1 passed a 100-mesh screen; 25 per cent of sample No. 2 and 90 per cent of sample No. 3 were also 100-mesh and finer. It will be observed that the richness of the sample varies directly with the fineness, the finest material being the richest.

Assay Methods.

In view of our comparatively meager knowledge of assay methods for metals of the platinum group, it would be unfair to all concerned to present the foregoing figures without an accompanying statement of the methods employed. The assay for platinum is usually made on sands containing metallics, or on alloys of the metal, and it is seldom that ores carrying the platinum group metals are presented for assay. The figures given in the foregoing tables do not represent *direct weights* of the metals indicated, but are calculated from *differences in the weights* of the buttons after successive partings with different acid solvents which are supposed to extract certain metals from the button.

The procedure is based on the following statements made by Lodge[6] and Fulton.[7] In an alloy of the precious metals,

(1) Sulphuric acid will dissolve silver and palladium together;

(2) Nitric acid will dissolve platinum when the ratio of silver to platinum is 12 or 15 to 1, or when the ratio of silver to gold to platinum is 15:2:1;

(3) Dilute aqua regia, 1:5, will dissolve gold;

(4) Concentrated aqua regia will dissolve iridium, and,

(5) The final residue insoluble in the foregoing treatment will be iridosmium and rhodium.

The method of assay used at the Rambler mine at present is as follows: Crucible fusions of ½ A.T. of material are made in duplicate. To one crucible is added silver in quantity about four times the weight of the precious metals believed to be present. As there is considerable copper and precious metal in the lead button, the cupellation is carried out at a high temperature, and if the resulting bead is large it is recupelled with an addition of lead to clean it thoroughly. The high temperature employed probably volatilizes any osmium and rubidium as oxides, so that these do not remain in the bead. The beads are dark gray in color, flat and rough.

The button to which no silver was added is weighed and calculated as total precious metals. The button alloyed with silver is parted with sulphuric acid and weighed. The difference in weight between this residue and the total precious metal button is calculated as silver and palladium. No further use is now made of this residue, unless it should be needed to replace a button lost in subsequent operations, or to check later results. The total precious metal button is now alloyed with silver, using 12 to 15 times the weight of residue from which silver and palladium have been dissolved.

This button is parted with nitric acid, specific gravity 1.20, and weighed, recording the differences in weight between it and the next preceding weight as platinum. The residue is then warmed with dilute aqua regia, 1:5, which will dissolve the gold, the weight of which is calculated by difference after another weighing. Finally the residue is boiled with strong aqua regia, dissolving iridium, which is estimated from the difference in weight between the residue and the next preceding it. The final weight gives iridosmium and rhodium. In alloying the cupelled buttons with silver in the first stage of the work it is noticed that small dark spots appear on the molten button, finally settling on the bottom when cold. These are probably iridium, which is exceedingly difficult to alloy. In making the partings it may be necessary to repeat the operation if for any reason it is feared that solution is incomplete, and this may be continued until a constant weight is obtained.

There are points in this procedure about which questions can be raised. It is doubtful whether the solvents used are without action other than that attributed to them, so that the final assay figures for any one of the metals may be high or low, due to incomplete solution of one of the constituents of the residue, or to partial solution of a constituent assumed to be insoluble. In any event, the total precious metal button can usually be relied upon, and the various constituents are reasonably correct.

[6] Notes on Assaying.
[7] A Manual of Fire Assaying.

This does not obviate the necessity or desirability of more exact procedure, and it is hoped that the production of high-grade precious metal concentrate at the Rambler will stimulate research in this direction.

Mention has been made of smelting operations carried on formerly at the Rambler mine. A matte smelter was erected in 1902 and operated for six or eight months, but finally abandoned as unsuccessful. Probably suitable fluxes were not available, and as the ore does not carry much iron, it was difficult to smelt. Samples of matte and copper bottoms taken from material on the dump showed, respectively, the presence of 17.00 oz. and 32.52 oz. of precious metal per ton of such material, thus showing the probability that precious metals have always occurred in the ore and have been lost in most of the previous shipments to copper reduction works. The data further indicate the possibility of gathering the precious metals in copper matte and blister copper. These facts, together with some work done for the Rambler company by the Chicago Copper Refining Company and FitzGerald & Bennie lead to a suggested system of metallurgy. The work referred to consisted in reducing some of the Rambler high-grade ore, producing blister copper. This was analyzed by FitzGerald & Bennie, with the following results:

Copper	91.1 per cent.
Precious metals	3.91 oz. per ton.
Silver	6.42 oz. per ton.
Lead	2.17 per cent.
Nickel	0.60 per cent.
Antimony	1.95 per cent.
Iron	0.90 per cent.

The lead was probably gathered from previous operation of the furnace, as it does not occur in the Rambler ore in any appreciable degree. Nickel has been identified in Rambler ores and antimony also occurs in small quantities, some authorities giving it as a constituent of sperrylite. It was from the electrolytic refining of such blister copper as this that the anode slime previously referred to was recovered and subsequently refined by Baker & Company and the S. S. White Company. .

In consideration of the foregoing data it would seem as though a rational system of metallurgy for Rambler ores would be the following: Direct smelting of the high-grade (25 to 30 per cent) copper ore, producing a matte subsequently to be blown to blister copper. Concentration of the low-grade (2 per cent) copper ore, recovering a high-grade precious metal concentrate which could be refined chemically, and a copper concentrate which could be smelted, blowing the resulting matte to blister copper; or, all of the valuable concentrate could be combined for smelting. The copper obtained from all smelting operations could be refined electrolytically and the anode slime containing the precious metals could be treated chemically. The copper carbonate and oxide minerals in the low-grade milling ore, which pass into the tailing pond, could be leached with the mine water, which is quite acid and also carries some copper in solution. The copper dissolved in this process could be precipitated on scrap iron, but the precious metal in the tailing would, for the present, have to await the development of some method of recovery. Or it might be found that it would pay to smelt 2 per cent copper tailings if the silica were not too high and the precious metal content were sufficiently valuable. The question of transportation would play a large part here. It will be apparent from the assays previously given that the concentration of the copper values in the low-grade ore would scarcely be profitable were it not for the precious metals recovered, but since the copper lost in the tailing and middling is almost all in a soluble form, the process outlined is expected to prove profitable and may be adopted.

The writer is indebted to Mr. W. J. Sherwood, mine manager for the Rambler Copper & Platinum Company, for permission to publish the data given herewith, and to Mr. A. C. Dart, consulting engineer, for courtesies extended.

Exploitation of Peat Bogs.

The exploitation of Canadian peat bogs for the production of fuel for domestic and industrial purposes was the subject of an interesting address, delivered last year before the American Peat Society by Dr. Eugene Haanel, Director of Mines, Ottawa, Ontario, Canada. This address has recently been published in form of a pamphlet, from which the following extracts are taken.

A former extended investigation of the manufacture of peat fuel, carried out by the Department of Mines of Canada, has demonstrated, firstly, that for the economic production of fuel from peat machinery driven by power must be substituted as far as possible for manual labor; and, secondly, that processes so far invented for removing the water content of the peat by pressure and artificial heat have not led to commercial results, and after trial have been abandoned.

Two promising processes employing artificial heat in the production of peat fuel have given disappointing results.

The Electropeat Syndicate erected an extensive plant at Kilberg, in the County of Kildare, Ireland, for the production of a substitute for coal from peat, which they expected to sell at six shillings per ton. No money was spared in trying to make the experiments a success, and most expensive machinery was put down. Experts were brought from Germany to look after the work under the superintendence of Captain Verey, R. E. Large shipping companies on the strength of samples submitted, and representations made to them, promised some very large contracts for fuel, but the company, at the end of over one year's experimentation, found that its process was a failure. The peat made by it looked like coal and burned well, but was hygroscopic, and after a short time crumbled to powder. All efforts to overcome this defect failed, and the project was permanently abandoned.

The Elkeberg process of the wet carbonization of peat is exceedingly ingenious, and has aroused great expectations, but is still in the experimental stage after the expenditure of 200,000 kronen in Sweden to place it upon a commercial basis.

The endeavor to accomplish *economically* by artificial means in a *short time* what has been accomplished by nature in exceedingly long periods of time, the change of peat into a substance similar to coal, has so far apparently not been attended with success. Dr. Haanel would not like to say that it cannot be done, since it is unsafe to make any statements regarding the possibilities of future achievement, but at present the outlook in this direction is not encouraging.

The proper course for Canada is, as Dr. Haanel points out, to introduce such processes and such machinery as have proved successful and are now in actual commercial operation in Europe.

To re-establish the confidence of the people of Canada in the value of peat as a domestic and industrial fuel and to stimulate renewed activity in the development of the great peat resources of Canada the government has acquired 300 acres of peat bog, with an average depth of 9 ft., for the purpose of manufacturing peat fuel on a commercial scale, and by a method which has proved successful in European practice. At this plant interested parties have an opportunity of ascertaining for themselves the working of the bog as well as the suitability of the peat fuel produced. The capacity of this plant is a production of 30 tons per day. For a large commercial plant mechanical excavators should replace the manual labor employed at this plant, if the bog to be exploited is suitable for this class of labor-saving machinery.

The plan at Alfred is to serve as a model of a successful process, and not for the production of peat fuel on an extensive scale. It was expected, however, to manufacture during the first season about 2000 tons of peat fuel, part of this to be used in their peat-gas producer at Ottawa.

There is nothing artistic about the appearance of the fuel produced at this bog. It has not the regular geometric form

of briquettes nor their smooth exterior, but it serves the purpose for which fuel is intended as well as briquettes, and has the advantage of being low in cost of manufacture.

Allowing 140 days for a season's operation, the cost per ton of air-dried machine peat, including interest on capital invested, amortization, oil and repairs, is given by Dr. Haanel as follows:

Cost of fuel on the field	$1.40
Cost of fuel stored in shed	1.65
Cost of fuel loaded on car	1.65
Cost of fuel in stack	1.70

By the employment of mechanical excavators and the manufacture of peat on a large scale, the cost of production per ton should be considerably less than the figures here given.

The objection to the air-drying process practised at this plant is that it is not a continuous process, that it can be worked only during the summer months, and that the amount of fuel which can be produced during one season is dependent upon weather conditions. But air-drying is employed successfully on a large scale in Europe, and especially in Russia, and the weather conditions in Canada are at least as favorable, if not more so.

The economy which may be effected by the use of peat in Canada is readily understood when it is stated that in Ontario and Quebec the average price of anthracite with a high percentage of ash is $7.50, and in Manitoba, $10.00 per ton, whereas air-dried machine peat, containing only about 5 per cent of ash can be manufactured at a cost of considerably under $3.00 for an amount having the same calorific value as a ton of the anthracite which must be imported. This could be sold at places conveniently situated as regards transportation facilities, and not too far from the place of manufacture for a little more than one-half the price paid for anthracite in Ontario and Quebec, and for a little more than one-third of the price paid for anthracite in Winnipeg.

Air-dried peat is not alone an excellent fuel for domestic use, but for the production of power it proves an ideal fuel in the peat-gas producer, which is to-day as reliable and efficient in its operation as the coal-gas producer. Dr. Haanel did not hesitate to say that it is an ideal fuel because the peat from most bogs is free from a clinkering ash and yields on combustion a fine, white residue, which readily allows of the thorough cleaning of the fire, and the property of not fusing or caking in the producer assures regular operation.

Moreover, since gas leaves the producer with a high degree of sensible heat, which must be cooled to the temperature of the atmosphere before being used in the gas engine, it is exceedingly important that as much of this sensible heat as possible be utilized in the producer itself, in order to increase its thermal efficiency. This is accomplished in coal-gas producers by the introduction of water vapor which passes through the incandescent fuel with the air supplied for combustion. This water vapor is decomposed, yielding hydrogen and oxygen. The latter combines with the carbon of the fuel, forming carbon monoxide.

This chemical reaction absorbs a large amount of heat and lowers the sensible heat of the gas, but the heat absorbed in liberating the hydrogen is to a large extent restored and utilized when the gas enriched by hydrogen is burned in the gas engine or other apparatus. With peat containing from 25 to 30 and more per cent of moisture the latter is sufficient to accomplish all that is required without the introduction of water in the producer from an outside source.

To demonstrate the value of peat for the production of power for industrial purposes a modern German peat-gas power plant has been erected by the Department in Ottawa. Its capacity is 60 hp, and consists of a double firezone Koerting peat-gas producer, with the necessary gas-cleaning apparatus, and a Koerting four-cycle single-acting gas engine direct connected to a Westinghouse 50-kw, direct-current generator.

The consumption of peat per brake horse-power is expected to be in the neighborhood of 2 lb., definite figures not yet being available.

The erection of gas producers designed for the recovery of by-products is not recommended except in localities where such by-products would command a ready and profitable market. In Canada it is far more economical to aim at the complete gasification of all the heat elements in the fuel.

Nucleus Action and Grain Growth

By HENRY M. HOWE.

The purpose of this note is to consider the explanation which Mr. E. Cohen gives of the interesting cases of nucleus action which he has observed.[1] He finds that tin which has been dulled in a certain way, when pressed against bright cold worked tin, such as tinfoil, or tin plate, inoculates these latter with like dullness, and that these infected spots thus set up can carry the infection to still others, slowly at room temperature (§ 4) and more rapidly at higher temperatures. (§§ 6, 13, 14.) What is the exact nature of this infection? The bright surface which he dulled in most of his experiments had been made by cold rolling or like action, and he explains the infection as an undoing of this cold rolling, reasonably calling the cold-rolled state metastable, and the non-cold-rolled state, that is, the dulled state to which infection brings it, the stable state ("forciert" and "nicht forciert," which we may translate as "overstrained" and "not overstrained," "ecroui" and "non-ecroui").

A prominent effect of overstrain, by whatever form of cold-working it is caused, is to distort the individual crystalline particles of which the metal is normally composed. Most metals, iron included, belong to the cubic (monometric) system; and the distortion incident to overstrain, of course, changes by different amounts the length of the several axes of any given crystalline grain, so that these grains, normally "equiaxed," become "inequiaxed." So we often refer to the "inequiaxing" caused by overstrain, and the "equiaxing" caused by annealing, one feature of which is that it restores the crystalline grains or particles to their normal state. But as tin belongs to the tetragonal (dimetric) system, with axes normally unequal, "equiaxing" and "inequiaxing" are not strictly applicable. Let us rather speak of "crystalline distortion" or "abnormal axing" and "crystalline readjustment," or "normal axing."

Applying these ideas to Mr. Cohen's experiments the initial bright state of his tinfoil and tin plate is one of crystalline distortion or abnormal axing, the diseased state; and the dulled state is one of cure, readjustment, or normal axing, in spite of the fact that here the cure is, as far as the practical applications of the tin are concerned, far worse than the disease.

The question which I wish to consider is, whether under Mr. Cohen's various conditions we can properly regard crystalline distortion and readjustment as the chief causes of the phenomena. Let us consider these phenomena.

A first case is that of the dulling of tin plate by reheating. Simple exposure to 161°, 176° and 184° did not cause dulling, though like exposure when coupled with contact with dulled tin did, and though Behrens found that bright faces of very greatly overstrained tin dulled at 110° and very rapidly at 150° (§17). This case falls readily into line. The molecular mobility caused by heating, and the nucleus action of dulled (readjusted or normal axed) crystals, are clearly allies, jointly favoring the readjustment (dulling) of distorted crystals. Hence it is but natural that their joint action should cause the crystalline readjustment of which dulling is but an evidence, even when heating alone fails to; and that the greater instability of Behrens's greatly distorted grains might cause them to submit to the tendency to readjustment, which heating to 150° or even only to 110° sets up, even though the less unstable grains of Cohen might defy this tendency to readjustment even at

[1] *Zeitschr. phys. Chemie*, 1909, **68**, *p.* 214. See also this journal, Vol. VIII, p. 510.

184°, unless it were reinforced by alliance with the nucleus action of dulled and normal-axed particles.

A second case is that careful oblique hammering on the bright surface of tin plate so as to destroy the polish sets up the dulling, which in turn dulls tinfoil pressed against it at 100°, setting up centers whence the dulling spreads. (§ 21.) This case, too, falls into line, if we assume that an exaggeration of the overstrain creates a degree of instability, an abnormality of axing, so great that the readjustment and normal axing occur, as in Behrens's case, without nucleus action. In short, the instability, when exaggerated, from being metastable becomes labile.

A third case may be considered. The watered (moiré) surface of etched tin plate dulls a bright tin plate when pressed against it at 184°, though two bright tin plates thus pressed do not dull each other, and though the watered surface is not affected by contact with dulled tin. (§§ 20-21.) To bring this into line we have to suppose that this watered look caused by etching is due to the readjustment and normal axing of the crystals, so that etched tin and dulled tin are alike in being normally axed.

A fourth case is less clear. The bright surface of a quietly frozen tin ingot is readily dulled by contact with dulled (infected) tin, whereas the surface and even the interior of a tin ingot shaken during freezing has the dulled look of infected tin, and has the power of dulling bright tin. In order to bring this into line we seem forced to assume that the bright surface of the quietly frozen ingot is in effect overstrained. When the metal is first poured freezing is likely to take place first at the bottom and sides of the ingot in contact with the cold mold. Later a thin skin freezes over the upper surface; and though this skin remains bright, its crystalline structure may misfit that which, spreading up quickly from bottom and sides, approaches it from below, so that the very skin may find itself in unstable crystalline equilibrium, not because itself abnormally axed, but because discordantly axed with regard to the mass underlying it. Or its own surface tension may so interfere with the crystallization of the very skin as to make it unstable. Because of this instability the surface may recrystallize and dull when to the influence of the underlying discordant crystals, or of its own instability, is superadded the influence of the dulled tin pressed on it from above.

But this explanation may be accused of bearing too much good will; and we find ourselves left with a desire either to clinch it by other and corroborative evidence, or to seek some further explanation. The amorphous state may give us the key.

In this connection there is great interest in Mr. Charpy's[1] discovery that previous overstrain accelerates enormously the growth of crystalline grain (Stead's brittleness) which occurs when very low carbon steel is held between 650° and 800°. Thus two like pieces of very low-carbon and moderately phosphoric steel, one wire drawn and the other not, were held in this range of rapid growth between 650° and 800°. After this the grains of the wire-drawn piece were about 10 times as wide as those of the other, implying a difference in volume of 1000 to 1. Steel which when wire drawn could be bent considerably without cracking, after later heating at about 650° became so brittle that it broke when dropped on the ground. Thus, though one effect of reheating wire-drawn steel is truly to anneal it, by normal axing and relieving stress, and perhaps in other ways, yet in case of very low-carbon steel an undue exposure to this very annealing temperature may cause a grain growth far more harmful than the abnormal axing and the stress which it removes. The cure of two diseases may here give rise to a third worse than those two.

That this growth should be rapid in this very low-carbon metal so heated is indeed natural. In the presence of much carbon the growth of the ferrite, whether alpha below Ac2 or beta between Ac2 and Ac3, is naturally impeded by the presence of the cementite. In very low-carbon steel the relative freedom from cementite removes this obstacle to growth. Of course, if the temperature rose past Ac2 so that the iron became beta the particles of this modification would be nascent during the change, and this nascency might well lead to extremely rapid crystalline growth. That the coarse grain should be effaced when, on rising past 900°, the iron changes into the gamma state is natural enough. The new state might well form new crystals of its own.

The reason for the acceleration of the crystalline growth caused by overstrain remains to be determined. Of course, the abnormally axed overstrained crystalline particles are initially in unstable equilibrium, so that to the impulse toward crystalline readjustment due to the mobility of the high temperature, say 750°, is added the impulse due to the initial instability, resulting in a greater rapidity of readjustment. One could hardly foresee that this should lead to a more rapid growth of grain; but the fact that it does is not unnatural, and may perhaps be likened to the lessening of friction which motion causes. Just as the mechanical friction of motion is far less than the mechanical friction of rest, so the anti-crystallogenic friction may be less in the overstrained metal because of the added rapidity of molecular motion caused by the instability due to initial overstrain.

The Death of Dr. F. A. Kjellin.

We regret to report the sudden death of Dr. F. A. Kjellin at the age of 38 years on Dec. 30, 1910. His name will be forever remembered for his connection with the development of the electric induction furnace. While others before him, especially Mr. E. A. Colby in this country, had invented and tried an induction furnace, Kjellin was the first to use it on a commercial scale, and he did important pioneer work in electric steel melting and refining.

THE LATE DR. F. A. KJELLIN.

Frederick Adolf Kjellin was born in the county of Vardinge, not far from Stockholm, Sweden, on April 27, 1872. He was educated at the Royal Technical Institute in Stockholm from which he graduated in 1893. During subsequent years he carried out a great deal of experimental work in chemistry and metallurgy, and worked out a new method for the electrolytic precipitation of zinc, on which method he obtained a patent. During the years 1893-1895 he assisted Professor Wiborgh in developing the well-known Wiborgh termofon for the determination of high temperatures. From 1895 to 1899 he was engaged in developing the Lux light now used extensively.

In the year 1899 he began at Gysinge his work on the use of the electric induction furnace for steel melting. In 1904 he became connected with the Swedish Gröndal-Kjellin Company, in the capacity as chief of the electrometallurgical department. During the last few years he acted as consulting engineer in this department. The honorary degree of Doctor of Philosophy was bestowed upon him by the University of Upsala in 1907.

The Manufacture of Ammonia-Alkali in England.

By Wm. Mason.

There is no branch of chemical industry in which the principles of engineering science have been so profitably applied as that of the manufacture of ammonia-alkali. The world's production of this article, which in 1883 was only 160,000 tons, has steadily increased until at the present time it is estimated to amount to upward of 2,000,000 tons per year, about nine-tenths of which is said to be produced by the Solvay system. The English Solvay works of Messrs. Brunner, Mond & Company, Ltd., in the Cheshire salt district, are the largest in the world and since the year 1881 have continued to show the most magnificent financial results.

It has been thought by some that the Solvay system was a secret method, but that is not so. This system works the method first made known by Schloesing and Roland in 1854, which is a modification of that practised by earlier workers, such as Dyar and Hemming, who obtained the first patent for this process in 1838. It is represented by the following equation:

$$Na\,Cl + NH_3 + CO_2 + H_2O = Na\,HCO_3 + NH_4\,Cl.$$

The ammonia-alkali process is so simple, so unlike the Leblanc process, that any one with only a little experience in chemical manipulation can produce sodium carbonate by it.

Solvay's first patent in 1863 was for plant, and a few years afterward he established works at Couillet, in Belgium, making in the first year 179 tons of soda ash. He was the first to make the manufacture of ammonia-alkali a financial success, increasing the production each year, until in 1874 he manufactured upward of 4678 tons, when it was introduced into England by the late Dr. Ludwig Mond with a success that is without a parallel in the history of chemical industry. The English Solvay works have paid an average dividend for the last 28 years of 31 per cent, the lowest in 1881 of 19 per cent, and the highest of 100 per cent in 1893.

Notwithstanding such success it can be shown that in the works of this successful company, when they were annually making a profit of nearly £200,000, in trying to improve the chemical side of this manufacture, they adopted and persistently worked a method which must have added at least 10 shillings per ton to the cost of production.

It has often been stated that in the carbonating part of this process a quantity of sodium bicarbonate remaining dissolved in the residual chloride liquors would always be lost, and to recover this bicarbonate Solvay suggests in one of his patents the placing of salt in the carbonating tower; but ordinary salt, as supplied to chemical works, contains impurities equal to 0.8 per cent, which increases the percentage of insoluble matter in the finished soda ash. In 1878 Dr. Mond obtained a patent for a method for purifying the brine by adding to it a kind of water-softening mixture; by this method he obtained a very pure salt. This process was worked for some time and then discontinued, ordinary salt being afterward used.

Now there is no evidence whatever to show that any of the salt added in this way was ever decomposed, or was necessary to prevent the loss of bicarbonate in these liquors. For this purpose about 10 cwts. of salt per ton of soda ash produced was required; this salt contained 10 per cent of water, which diluted the liquors, the dilution being further increased by 50 per cent more water being required to wash out the excess of salt from the bicarbonate. This water carried away bicarbonate in solution, thus making more liquor to be passed through the ammonia still, which increased very considerably the cost of manufacture.

Below are given some analyses of the residual liquors: No. 1 from Solvay towers having had salt placed in them; No. 2, from another works which did not use salt in the carbonating apparatus, while No. 3 gives the analysis of liquors from Solvay towers after finding out that salt was not required to obtain a residual liquor from the carbonating tower, with little or no sodium bicarbonate in solution:

No. 1. Solvay Tower Liquor with Salt Added.

Percentage alkalinity calculated as NH_3	1.49	1.19	1.61	2.22
Ammonium chloride	16.53	17.12	16.42	14.29
Sodium chloride	13.11	12.98	12.29	14.98

No. 2. Carbonator Liquor without Salt.

Percentage alkalinity calculated as NH_3	1.65	1.87	1.56	1.63
Ammonium chloride	18.88	17.97	18.08	17.33
Sodium chloride	6.88	7.28	7.74	8.00

No. 3. Solvay Tower Liquor without Salt.

Percentage alkalinity calculated as NH_3	2.02
Ammonium chloride	17.22
Sodium chloride	8.45

Since for every equivalent of ammonium chloride produced an equivalent of sodium carbonate is precipitated as sodium bicarbonate, analyses Nos. 2 and 3 clearly show that slightly better results were obtained than by the addition of salt.

Although this process is an English one, it was not worked in England until the year 1874, when works were built at Northwich, and a year later at Sandbach. In 1874 Solvay manufactured upward of 4678 tons and it is evident that the works mentioned above were of the same capacity. They are very clearly described by him in the specifications of patents No. 999 and No. 1904, of 1876. The plant at Sandbach consists of lime kilns, four ammonia stills with heater and absorbers, five carbonating towers, four drying machines, besides other vessels. When working this plant showed a profitable return, but it was almost impossible to keep it continually working because of its extremely complicated parts, chiefly in the ammonia stills, the connecting pipes becoming blocked and the changing valve leaking. Moreover, the lime, being charged unslaked, was very badly burned.

Through these causes it might safely be said that the plant did not work more than two-thirds of its time, yet with all its drawbacks this plant was working in the year 1881. This plant could never have competed favorably with the Leblanc process and the ammonia alkali industry was in a most critical condition when the late Dr. Ludwig Mond, from the capacity of the ammonia distilling apparatus of this plant, designed the vertical still afterward patented by him in the year 1883.

This still is a fine example of chemical engineering, as it shows how the principles of engineering may be applied in the construction of chemical plant; it was such an improvement over the four-still arrangement that the daily output was increased by more than one-third, that is, from 13 tons to more than 21 tons, without increasing the other parts of the plant; in fact, this vertical still made the plant almost continuous, having only to be stopped a day in about six weeks.

This plant was duplicated and worked most successfully for many years. A vertical still had been used in distilling ammoniacal liquors long before this time, and it seems strange that it was not used at first, as it was much cheaper to construct. Solvay describes one in his specifications of patents for 1876.

The carbonating tower patented by Solvay in 1872 is also an apparatus which shows a considerable amount of engineering skill and may be considered his best contribution to this particular process and it still remains a part of the present-day plant with the addition only of an internal cooling coil.

Although the patent protecting this Solvay carbonating tower, which was so ingeniously designed and which produces the most perfect results in working, became void in 1886, another works was established at Runcorn which contained a plant much simpler in construction than that of Solvay; in fact, it consisted chiefly of large cylindrical vessels made of boiler plate to the number of about 30. It was worked as follows:

The ammoniacal gases from the stills, without cooling, passed into vessels called saturators which contained salt-brine and into which solid salt was also charged by means of a cage run-

ning down the length of the saturator, so that brine was made and saturated with ammonia in one operation. The ammoniated brine so produced was similar to that obtained in the Solvay system.

The great drawback of this method was that much salt became deposited in the saturators, sometimes to the depth of 12 ft. or more, which made it difficult to estimate the ammonia in them, a matter of the greatest importance in this process. The stills in this department on several occasions recovered upward of 620 lb. NH_3 in the hour.

From the saturators the ammoniated brine, after cooling and settling, was passed into vessels called absorbers, two in number, so that while one was being filled with ammoniated brine the other was working as a part of the carbonating plant. The carbonating plant consisted of three vessels, each containing about 600 cu. ft. of ammoniated brine. The carbonic acid gas from the lime kiln, after being washed and cooled and at an initial pressure of 38 lb. per square inch, passed through these concentrators, through an absorber, then through a tank containing brine and lastly through a vessel containing acid.

Five carbonators were worked off during the day of 24 hours and produced about 10 tons of soda ash. The washing of the soda bicarbonate was so carried out that about 20 per cent of it was washed away and lost. Analyses of residual liquors from above carbonators have already been given above (Table No. 2).

By the Solvay towers the 600 cu. ft. of ammoniated brine could have been worked off in less than three hours, that is, in the state of carbonation as it passed into these carbonators, and at least 15 tons of soda ash might have been produced instead of 10 tons. The plant was supposed to contain a quantity of ammonia equal to 55,000 lb. NH_3, a quantity quite sufficient for a daily output of 35 tons of finished soda ash. Sixteen tons of limestone were also burnt per day. A particular feature in this plant was that the vessels were so placed that the liquor passed by gravity from vessel to vessel so that pumps were not required. This works was not a success.

At Middlewich, in 1889, a plant very similar to the one already described was erected, but on a much more extensive scale. It contained two large ammonia stills very similar in construction to the Mond still mentioned in the Solvay system, except that the superheater was connected by pipes instead of being built in one column. It also contained four sets of carbonators similarly worked as at Runcorn, and four lime kilns. With a little ingenuity this plant might have produced at least 600 tons of soda ash per week; with the whole plant working only 300 tons were made and with half the plant but 200 tons of soda ash were produced per week.

To illustrate this point two examples will be given. When the whole plant was working and contained a quantity of ammonia equal to 123,000 lb. NH_3, 104 tons of limestone were burnt, 16,000 cu. ft. of residual liquor distilled, 15,000 cu. ft of brine used; 55.8 tons of soda ash were produced in the day of 24 hours. To effect this about 20 carbonators were worked, each containing 840 cu. ft. of ammoniated brine.

Another example when only half the plant was working and contained a quantity of ammonia equal to 57,000 lb. NH_3: 6600 cu. ft. of residual liquor were distilled, 6600 cu. ft. of brine used; 23.68 tons of soda ash were produced; about 10 carbonators were worked off. The loss of ammonia in the working of this plant varied from 3 per cent to 15 per cent, that is, parts of ammonium sulphate per 100 parts of soda ash. This works in the year 1893 with a capital of some £180,000 lost £10,680 on the year's working.

Another works with about the same amount of capital paid only 7½ per cent dividend. In fact, three works of very similar construction were bought up by Messrs. Brunner, Mond & Company, Ltd. If these works had used the Solvay tower or had used more engineering skill in the construction and working of their plants much more favorable returns would have been made.

Similar intermittent plants have also been worked in different parts of Germany about 30 years ago, all of which are said to have failed. None of these intermittent systems could ever succeed against the Solvay system and the price of alkali need not have been lowered to £2.175 6d. per ton, as it must have cost more than £4 per ton to produce soda ash by them.

Islip, Oxford

Cyanidation of Ores.*

By Dr. Wilbur A. Hendryx.

The chemistry of the cyanide process is so well known and universally accepted as commercially correct that I will pass it over, as the object of this paper is to deal with the mechanical handling of ores and the different apparatus employed.

For convenience sake I will divide the ores into four classes:

1. The silicious ores, requiring amalgamation and cyanidation only.

2. Ores containing, besides silica, iron, lead, zinc and copper sulphides, etc., in which amalgamation and cyanidation recover a large percentage of the gold and silver contents. (The precious metals being physically combined.)

3. Ores containing sulphides in which a portion of the gold and silver is chemically combined and at the same time carry a larger percentage of cyanicides, which can be removed by concentration before subjecting them to cyanidation.

4. The sulpho-tellurides, which up to the present time require roasting to put them in a condition to be transferred from the fourth class to the first.

It has been my practice for years to grind all ores and tailings which are to be cyanided to a sufficient degree of fineness to permit the solutions to come readily in contact with the metal which is to be extracted, whether it was ¼ in. or 200 mesh.

I will first refer to the mechanical devices and arrangement of the same for the class of ores arranged under the head of class 1.

I preferably use two rock breakers and deliver to the stamps a product not larger than 1 in. The stamps most commonly used weigh 1050 lb. each and drop 100 to 105 times a minute. A 12-mesh to 16-mesh screen is used, thereby giving from five to eight tons to the stamps per 24 hours, with approximately four tons of solution to one ton of ore. I use the word "solution" instead of "water" because I invariably find where wet crushing is resorted to a weak alkaline solution of cyanide (1/40 of 1 per cent or less) increases the amalgamation of the gold and silver, except where it is prohibitory owing to the presence of a large amount of cyanicides, necessitating concentration, as in the case of ores I have placed in the third class. Not only is amalgamation increased by crushing in cyanide, but considerable gold is put into solution at the battery; consequently, as a general rule, the best practice is to begin cyaniding at the battery.

Dropping the subject of wet crushing for a moment and taking up the ores of class 4, namely, sulpho-tellurides which require roasting, my experience has led me to believe that the most economical apparatus on the market to-day for reducing the ore to the proper mesh dry, after the rock breaker, before it goes to the roasting furnace, is that type of mill known as the Bonnot mill or Kominuter. While they are not adapted to wet grinding they are particularly efficient in dry grinding. Of course, there are many varieties of rolls, some of which are also adapted to dry grinding.

Referring again to wet crushing with stamps I believe up to this point we have reached the greatest capacity and economy. The next step after the stamps is amalgamation if coarse gold is present. After the plates a dewatering sizer is used so that the ore which has been ground fine enough to permit the solutions to come in contact with the gold and silver is classified out and taken to a storage settler, preferably a Hendryx combination agitator and filter, which in that instance acts as a

*Abstract of a paper presented before the Scientific Society of Colorado.

storage settler (up to the time of its having received its proper charge of solids, when it is then used as an agitator and filter) together with three-fourths of the solution from the battery, while the coarser, or over-size, is fed to a tube mill and ground to the proper fineness and discharged into the same storage settler, or agitator, acting as a storage settler, that the fines from the classifier were discharged into, where sands and slimes are brought together for succeeding treatment without further separation, thus permitting the reduction of the amount of solution before the ore is agitated to the proportion of one, two or three to one, by weight if so desired.

I have never found an ore in which the values could be extracted by leaching in two, four, six or eight days that as good or better extraction could not be made by proper and thorough agitation and aeration in the same number of hours. For that reason it is my practice to agitate sands and slimes together.

In placing the tube mill in the position above indicated in the mill I do not wish to be understood that all ores must be tube-milled, or finely ground, but that the great majority do I think is generally conceded.

The tube mill, or pebble mill, has within the past few years been brought to such a state of perfection that, in my opinion, it is far more economical to use a coarse screen in the battery and get the full efficiency of the stamps and finish with the tube mill. I prefer to use the tube mill because it has many advantages in fine grinding, such as dispensing with fine screens, which cause a continuous expense and which become clogged with finely ground wood pulp and other debris mixed with the ore, thereby reducing the capacity of the battery; the silex lining and flint pebbles do not cause a loss of cyanide as does the finely ground metal produced from the wearing parts of the iron or steel grinding machines. The wear of pebbles is much less in number of pounds and at a much less cost per pound than steel.

When sufficient ore and solution (say two to one) has accumulated in the agitator, acting as a storage settler, potassium cyanide is added to bring the solution up to a strength of from ½ lb. to 1 lb. per ton of solution for the average gold ores and not to exceed 1½ lb. per ton of solution for the average silver ore, and ½ lb. to 1 lb. of protective alkalinity (usually procured from calcium hydroxide), then the agitator is started and the ore pulp is agitated from two to eight hours for average gold ores and from eight to twenty-four hours for average silver ores. I have found many more ores that can be treated in two hours than those requiring twenty-four or more hours. During this period of agitation a second combination agitator and filter is used as a storage settler while agitator No. 1 is doing its agitating and filtering.

We have now only treated of that portion of the solutions which have remained in the agitator and are to be used for dissolving of the remainder of the precious metals which were not dissolved while passing through the grinding department. The surplus solution which has been taken off, if found to contain sufficient of the dissolved values and which has accumulated in the precipitation tank is mixed with zinc dust and passed through the zinc dust press, and having left its gold and silver values in the press is now termed "a barren solution." It is either run to the battery supply tank or to a barren solution tank above the agitator, where it is conveniently stored for the first wash of the tailings after the rich solutions have been filtered off from the agitator.

When the dissolving is completed in the agitator 80 per cent of the solution is drawn off through the filter cells and bottom canvas of the agitator and run to the precipitation tank above referred to, then the barren solution is drawn from its above-mentioned tank and introduced as a wash underneath the canvas in the agitator and through the filter cells and the agitator started and the whole mass put in a perfect mix. The agitator is then stopped and the filter cell cocks are opened and another 80 per cent of this solution, which is equal to 16 per cent of the original solution, is taken off. Then the same amount of fresh water that is to be finally lost in the tailings is added to the agitator on top of the settled charge and is drawn downward through the bottom canvas, displacing the remaining barren solution which was mixed with the remaining rich solution, or the charge is again mixed and discharged to the dewaterer.

By either procedure nearly the whole dissolved values have been recovered. This operation is made possible owing to the perfect homogeneous mix procured in this agitator. When the agitator shaft is stopped all the granular matter settles regardless of its mesh and covers the bottom canvas, thus forming a most perfect sand filter next to the canvas which will remain free from slimes sufficiently long to permit an ordinary suction pump to draw out the remaining solutions so that the remaining moisture in the pulp will not contain more than 20 per cent of moisture. (Fig. 1.)

The tailings are then ready to receive sufficient water (say 50 per cent) to allow them to be discharged from the agitator. They may be either discharged to the waste dump, if abundance

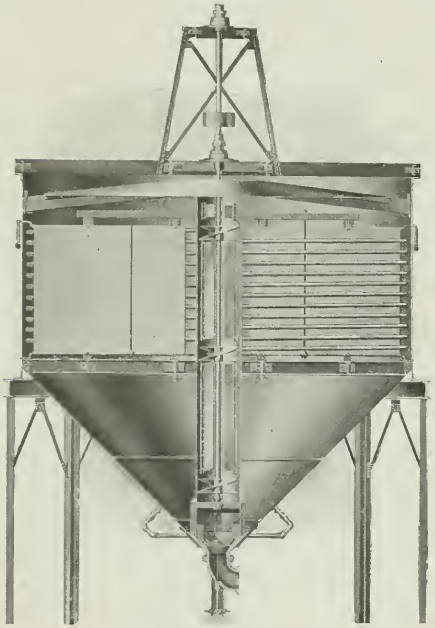

FIG. 1.—COMBINED AGITATOR AND FILTER.

of water is accessible, or if there is no objection to their flowing to the dump. In the event of greater economy being desirable owing to the lack of water, or owing to the fact that the tailings must be stacked in order to keep them from contaminating streams or flowing on to adjacent property, then they should be discharged into the dewatering device. (Fig. 2.)

After the addition of the wash water above mentioned, if it has been mixed with the remaining 4 per cent of the remaining pregnant solutions and barren solution, it should then be discharged to the dewaterer. The gold and silver filtered solutions are passed to the zinc precipitation tanks and pumped through the zinc dust press and returned to the battery storage tank or to the barren solution tank above the agitator. If there is not found enough alkalinity to protect the cyanide remaining in the solutions after passing through the zinc dust, which is often the case in heavy sulphide ores, caustic soda or hydroxide of lime should be added to the battery solution tank from time to time in order to maintain a constant alkaline condition of the solution.

My experience has led me to adopt precipitation by zinc dust because the cost of operation is extremely low and besides almost complete precipitation is possible from a solution containing 1 lb. of cyanide or less per ton, thus making it possible to carry out the general scheme of using weak solutions all through the mill. The use of weak solutions lessens the liability of fouling, which occurs to a greater extent when strong solutions are used.

I do not believe any one who has had considerable experience in electrolytic work will presume to make the claim that a solution containing metals can be rendered barren of its metallic contents economically. On the other hand, there is a class of ore in which the solution becomes so fouled that it is extremely difficult, if not impossible, to successfully and economically precipitate the values on zinc. I have found that the introduction of electrolytic deposition in combination with zinc dust tends not only to regenerate the cyanide, but will deposit out the base metals, together with the gold and silver, leaving the solution in condition so that when passed through the zinc dust complete precipitation of the remaining gold and silver values is effected.

Combination Agitator and Filter

By referring to Fig. 1 it will not be necessary to describe the plain agitator, as the only difference between the two is the addition of the filter cells and the bottom canvas in order to convert the plain agitator to the so-called combination agitator and filter.

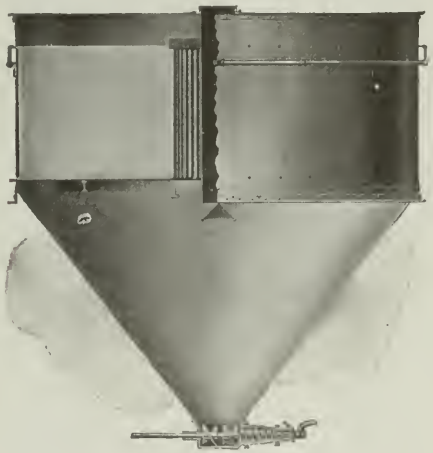

FIG. 2—DEWATERER.

The Hendryx combination agitator and filter consists essentially of four parts: a tank with converging bottom within which are centrally located an agitating pump, a series of filter cells, and a system of coils of pipes for heating the solution.

The tank is made of sheet steel and has a 45° bottom. A quick-acting discharge valve is located at the apex of the sloping bottom. Over the bottom of the tank is fastened a canvas sheet, which serves the purpose of evenly distributing the inflowing wash solution and allows the displacement of the solution remaining in the ground ore either upward or downward.

The agitating pump consists of a large well, within which is located a shaft carrying propellers. At the top of the well is a distributing and aerating apron which extends nearly to the sides of the tank.

The filter cells are located vertically beneath the distributing and aerating apron and consist of a wooden frame with iron tees and elbows. A piece of cocoa matting or wood strips fills the inside of the frame. The entire frame is enveloped in canvas, and the canvas and cocoa matting are quilted together at intervals. The filtered solution flows from a tee at a lower corner of the frame, while a tee at an upper corner serves the purpose of introducing air or wash solution to clean the cell.

The method of operating of the machine is somewhat as follows, although it may be varied to suit individual cases: Ore and solution in the proportion of about two of solution to one of ore, by weight, are accumulated either in the agitator or run in from storage until the tank is filled to nearly the bottom of the distributing and aerating apron. The agitating pump is then started and agitation continued until the soluble gold and silver have been put into solution. At the same time the solution is heated to about 90° Fahr. by means of hot water or steam circulating through the coils of heating pipe.

After the charge has been heated, agitated and aerated for a suitable time agitation is stopped, and the separate outlets to the filter cells are opened, allowing the solution to filter off by means of gravity. Owing to the perfect mixing in the agitator, when the power is shut off, a perfect classification of coarse and fine particles of ore takes place, so that the canvas in the bottom of the agitator has an ideal sand filter covering. This permits of the introduction of wash solution on top of the charge.

After filtering off approximately 70 per cent to 80 per cent of the original solution through the vertical cells and through the filter on the conical bottom, then by use of an ordinary suction pump, a downward displacement can be quickly accomplished. The downward displacement requires much less volume of water or displacing solution than the upward displacement and less time in the great majority of cases.

By the use of violent and rapid agitation and heat the slime is coagulated or curdled, so that it settles rapidly. Vacuum or pressure is not required on the filter cells, the solution filtering off by gravity alone.

Mechanical agitation is the only method of agitation that puts the charge in this condition, and the only method which gives the shortest time for dissolution, as the mechanical agitator with the same horse-power will circulate the ore pulp ten times as rapidly as the air agitator.

Air agitation also causes emulsification of the slime, thereby retarding filtration, prohibiting settling of the charge for decantation, introducing an excess of air containing carbon dioxide, which is a cyanicide, also permits of the introduction of oil from the use of a compressor, which still further emulsifies the solution and forms hydrocarbons, another source of cyanide loss.

A machine of this character capable of agitating and filtering 100 tons of average gold ores per day requires only 6 hp. With this machine the solutions can be readily changed; that is, 80 per cent or less as desired of the first solution can be taken off and a fresh solution added which, it has been found in the treatment of some of the silver ores, decreases the time of treatment as much as 25 per cent.

Storage or Tailings Dewaterer.

This dewaterer is designed to remove the water or solution from concentrates or tailings and deliver the same in such condition that they can be conveyed away on a belt or in a car and stacked. The solution or water is recovered in a clear condition and returned for further use.

It is also used in the case where only one agitator is installed to thicken slimes and to collect and hold the ground ore until such time as a sufficient tonnage has accumulated to make a charge for the agitator, when it is discharged. The excess solution to the dewaterer from the crushing department having been recovered and returned to the grinding department.

Where the water supply is limited, with this dewaterer the mill capacity will be more than doubled besides making a closer saving of the values and preventing the loss of cyanide and chemicals in the discharged tailings.

This machine without the use of vacuum or pressure will de-

water 200-mesh tailings down to from 12 per cent to 20 per cent moisture.

This apparatus consists of a round tank with a conical bottom. Within the tank are placed vertical filter cells for the purpose of clarifying the solution or water. At the bottom of the cone is an outlet within which is a screw connected to a shaft, which is revolved.

The tailings as they settle are removed from the conical bottom and forced through the outlet by the revolving screw in a continuous stream. The screw is run at a very slow speed, hence there is very little wear on any of the working parts.

This machine is used after the combination agitator and filter in order to recover the wash solution and fresh-water wash, thereby making the highest possible saving of chemicals and also shortening the time in the combination agitator and filter, and thereby increasing its capacity.

The Analysis of Aluminium Alloys.

By Thorn Smith.

The methods for the analysis of aluminium alloys as given in many textbooks are crude and inapplicable, so much so that one is very apt to conclude that the writers have had no experience and are merely describing methods which they think are applicable. Much annoyance and loss of time follow when their application is attempted by the chemist who but seldom has occasion to use them. Time and again the estimation of aluminium by precipitation with ammonia has been proven worthless in the hands of the ordinary chemist, yet textbook writers persist in giving the method first place; in fact, it is generally the only one given. To suggest that 1 gram of aluminium can be weighed out, dissolved in caustic soda, made acid wth hydrochloric, and precipitated as hydroxide with ammonia, then filtered, washed and ignited, is beyond reason and, to speak plainly, ridiculous. So much has been written on this method of procedure as usually carried out that further comment at this time is unnecessary.

It is sufficient to say that at the present time there is no method for the direct estimation of aluminium in alloys high in this element and that the amount present as obtained by difference is the best that can be done. Therefore, if even the approximate percentage be desired, it is essential that care be taken in estimating the other elements in the alloy and that the chemist have a full understanding of their solubilities and interferences. Considerable latitude must be allowed as the various alloys are radically different and the procedure may be greatly shortened in many cases. New methods are not common, but the older methods can in many instances be shortened and presented in a new light. The present article is written to help those who but seldom have use for such methods and at the same time to furnish thinking points for those who have occasion to analyze these alloys frequently.

Analysis of Commercial Aluminiums.

The two impurities present are silicon and iron. Neither of these present any difficulty if ordinary precautions are taken.

Silicon.—Dissolve 1 gram of the drillings in 30 cc of the following mixture: Nitric, 1 part; hydrochloric, 3 parts; sulphuric, 2 parts, and water, 4 parts. A 4-in. porcelain casserole well covered is the best for dissolving the drillings. When violent action ceases, add an additional 5 cc of sulphuric acid and take rapidly down to white fumes. This is quickly done when the solution is nearly evaporated by rapidly rotating the casserole over an open burner. Taking down to complete dryness or evaporating off the excess sulphuric acid is unnecessary. Allow to cool and add 50 cc of cold water, stir, and boil until the sulphates are in solution, a point easily noted. Filter *at once,* washing with hot water, containing a little HCl, several times and finally with hot water alone until the filtrate is free from chlorides. Ignite the moist precipitate in an unweighed platinum crucible and after the paper is destroyed blast for at least five minutes. Cool and weigh. To the crucible add 1 drop of sulphuric acid and 10 drops of hydrofluoric acid. Evaporate on the hot plate to the drop of sulphuric acid, then heat cautiously over a burner until the sulphuric is expelled. Blast five minutes, cool and weigh. Factor 0.4693 equals silicon. There should be no appreciable residue left in the crucible.

Iron.—Contrary to the usual manner of estimating the iron by reducing the silicon filtrate and titrating with permanganate a separate portion of from 2 grams to 5 grams is weighed into a No. 3 beaker and from 10 cc to 20 cc of 1 to 1 hydrochloric acid cautiously added. When in solution boil a few minutes and add a drop or two of stannous chloride to reduce any iron that may have been oxidized. From this point titrate with normal twentieth, or weaker, permanganate solution, using a titrating mixture and following some definite method of procedure, preferably that used by the United States Steel Corporation, as described in the February, 1909, number of this journal (Vol. VII, page 65). It is important that the permanganate be standardized in the same manner. Another point of no less importance is the titration of an iron-free blank and deducting this figure from all titrations even in standardizing. With these precautions the results are accurate, providing titanium is absent.

Aluminium Alloys.

The one most commonly in use contains from 5 per cent to 10 per cent of copper in addition to the impurities mentioned above.

The silicon is estimated in the same manner. For the iron proceed as above until solution is effected, dilute slightly with water, filter and wash two or three times with hot water. Heat to boiling, reduce with tin solution and titrate as above. The little copper that goes into solution does no harm. The iron usually present in the alloy is so small and the solution so strongly acid that the amount held up by the copper is negligible.

Copper.—A 1-gram or 2-gram weight is taken, depending on the amount of copper present. Place in a No. 3 beaker, add 5 grams or more of sodium hydroxide and enough water to cover. When action ceases add 200 cc of hot water and boil five minutes or more. Filter and wash once with hot water. Dissolve the precipitate on the filter with 1 to 1 nitric acid, allowing the filtrate to run into the beaker in which the alloy was dissolved. Wash the paper three or four times, then pour on ammonia until the solution is deep blue. If the filter paper is colored blue, due to copper, wash again. To the blue solution, which should not exceed 125 cc, add 2 cc each of sulphuric and nitric acids. This amount should make the solution acid. Electrolyze.

Columns might be written on the electrolytic method of determining copper, so confusing are the textbook methods. Suffice to say that given a copper solution which may contain any or all of iron, aluminium, zinc and manganese the plating process is simple. Whatever form of cathode is employed the main precaution to be observed is the avoidance of too heavy a current, which will cause sponging or blackening of the deposited metal. The voltage may be ignored providing it is not too low; in other words, a 125-volt, direct-current lighting circuit may be used successfully. The rate at which the electrolyte gases is the best measure of the amount of current to use and a little experience is sufficient to guide one.

While for first-class work the electrolytic method is to be preferred, there are times when the chemist may prefer to use the cyanide method. To this there is no objection providing a strict method of procedure be followed. In dissolving the copper precipitate use 10 cc of 1 to 1 nitric acid in every case. Wash the paper thoroughly and boil off the nitrous fumes. Cool and add 10 cc of ammonia. Make up to a definite volume, preferably 100 cc and titrate with KCN, 1 cc of which equals 2/10 per cent of copper. In standardizing the cyanide the metallic copper should be dissolved in 5 cc of nitric acid and

made alkaline with 10 cc of ammonia. The volume should be the same as before. It is best to titrate to a faint pink color rather than to the complete discharge of the blue color. The addition of the cyanide should be very slow as the end point is approached. The presence of iron, etc., in the solution does no harm and it is a waste of time to remove them. The main precaution is that the operator is sure that he has all of the copper in the solution which he is titrating that originally existed in the alloy. The addition of hydrogen sulphide to the solution before separating the metallic copper by filtration is advisable. If much sulphide is thrown down it is well to use a little bromine water with the 1 to 1 nitric acid. The same amounts of acid and ammonia should be used in every titration and in titrating the operator should not go too far. Much time may be saved by having a standard solution of copper on hand made by dissolving 2 grams of copper foil in as little nitric acid as possible and diluting to 1 liter. Determine the copper in 25 cc of this solution by the electrolytic method. In using this solution as a standard do not omit the addition of 5 cc of nitric acid.

When the alloy contains *zinc* in addition to the iron and silicon proceed as before for these elements. For the zinc dissolve 0.5 gram to 1 gram, or more, of the alloy in dilute hydrochloric acid, boil a few minutes and cool. Make up to a volume of about 100 cc, add three drops of methyl orange, then sodium bicarbonate, until the solution is just straw color. Now add 20 per cent formic acid, drop by drop, until the solution again shows acid, then add five drops in excess. Dilute to 200 cc or 300 cc with hot water and heat to very near boiling. To this hot solution run in hydrogen sulphide until precipitation is complete. Allow the precipitate of zinc sulphide to settle, filter and wash by decantation three times, using hot water. Wash the paper to remove aluminium, then throw back into the beaker in which the precipitation was made; add 50 cc of hot water and 10 cc of hydrochloric acid. Boil until the zinc sulphide is completely dissolved. Filter, washing with hot water containing a few drops of hydrochloric acid. Boil off the hydrogen sulphide and add a few drops of bromine water to oxidize any possible iron. Cool slightly and add ammonia in excess. Boil and filter. If the precipitate is more than a trace reprecipitate. Now make the solution slightly acid with hydrochloric and add a *large* excess of sodium or ammonium phosphate. Make just alkaline to litmus paper with ammonia, then add 1 cc of strong acetic acid. Warm until the zinc phosphate is crystalline in appearance, which requires but a few minutes. Allow to settle, filter and wash by decantation several times with hot water before adding the precipitate to the filter. Dry the paper and precipitate, detach the latter and burn the paper in a porcelain crucible. Then add the precipitate and ignite very gently at first, increasing the heat gradually and finally heat to bright redness for five minutes. Factor 0.4291 equals zinc

This is at present the most accurate method we have for the determination of zinc. Too much emphasis cannot be laid on the use of an excess of the phosphate salt.

Where strict accuracy is not desired titrating with ferrocyanide is very satisfactory, the results depending on the experience of the analyst with the method and the strict observance of uniformity in all operations.

When copper is present with the zinc it is better to dissolve a weighed portion in sodium hydroxide, dilute to 200 cc and heat to boiling. Precipitate the copper and zinc together as sulphides. The presence of the copper permits the filtering of the mixed sulphides without the usual running through the filter paper. Wash once with water containing hydrogen sulphide to remove the greater part of the aluminum. Place filter and contents back into the beaker in which the precipitation was made; add 50 cc of hot water and 10 cc of hydrochloric acid. Boil to dissolve the zinc sulphide and filter. Wash with water containing a few drops of hydrochloric acid and a little hydrogen sulphide. Boil off the hydrogen sulphide, add bromine water and proceed as before, making a double separation with ammonia if the aluminium is in much evidence. From this point proceed as above.

The estimation of *manganese* is frequently desirable and there is no method to equal the "Bismuthate." A weighed portion up to 5 grams is dissolved in sodium hydroxide, diluted, boiled and filtered. The manganese is on the filter. Dissolve by pouring on 50 cc of nitric acid, sp. gr. 1.135, containing a few drops of sulphurous acid. From this point proceed with the bismuthate method.

Tin, antimony, lead, nickel, titanium and even other elements may be found at times, depending on the source of the alloy or the use to which it is to be put. None of these present material difficulty and can be estimated by well-known methods.

In conclusion, the chief causes of poor results are: The impossibility of securing an even approximate result by estimating aluminium in the usual manner. This is increased by the use of glassware in precipitating.

The attempt to estimate iron on too small a weight of the material. The attempt to precipitate and filter zinc from an alkaline solution in place of the newer and better method using formic acid.

The failure to adhere strictly to methods as given and making no departure until convinced by repeated experiment that harm will not be done.

Note.—The reader is referred to the following publications for more detailed descriptions of methods mentioned in this article: *Bulletin* 304 U. S. Geolog. Survey; *Journal* of the American Chemical Society, volume 26, page 4, and volume 29, page 262. Blair's "Chemical Analysis of Iron" for the bismuthate method.

Detroit, Mich.

Formulas for Pinch Phenomenon.

By Carl Hering.

The internal electromagnetic force, which acts to contract the cross-section of a conductor, due to the current, and which is now known as the pinch phenomenon, occasionally enters into calculations, especially in connection with electric furnaces in which there is a liquid resister in which such relatively small forces can act and must therefore be considered. In such cases it is desirable to have the formulas for calculating it in convenient form for direct use, as errors often arise in reducing a formula from one kind of units to another. The purpose of the present note is to give these formulas in their different forms.

The original formula deduced by Dr. Northrup[1] was intended for a particular purpose and is not in the most convenient form for direct application to furnaces. It is in pounds per square centimeter, a unit of pressure seldom used, and it contains as two factors the cross-section and the current density, hence the latter depends on the former.

Omitting the factor n, which is unity in the general case, this original formula is as follows:

$$P = \frac{S\,C^2}{44{,}479{,}100} \qquad (1)$$

P = pressure in pounds per square centimeter.
S = section square centimeter.
C = current density in amperes per square centimeter.

It applies strictly only to cylindrical conductors. P is the pressure at the center. The constant is a purely mathematical one and involves no empirical determinations.

In the form thus given the formula brings out the interesting fact that the pressure increases as the *square* of the current density. This, however, is somewhat deceptive in that when the current density is increased by diminishing the section then

[1] "Some Newly Observed Manifestations of Forces in the Interior of an Electric Conductor," *Physical Review* Vol. XXIV, No. 6, June, 1907, p. 474.

the pressure will not increase in that proportion because the other factor S will be decreased also. It is for this reason that the writer does not favor the use of such interdependent quantities in formulas when it is just as easy to use entirely independent ones.

By reducing it to English units and eliminating the current density, hence using only independent factors, the formula reduces to

$$P = 0.000,000,022,482,5 \frac{C^2}{S} \qquad (2)$$

P = pounds per square inch.
S = square inches.
C = current in amperes.

To reduce this awkward constant to a simpler one the cross-section may be represented in square mils and the formula will then reduce to

$$P = 0.022,482,5 \frac{C^2}{S} \qquad (3)$$

P = pounds per square inch.
S = square mils.
C = amperes.

To reduce it to the metric system it is preferable to express the cross-section in square millimeters instead of square centimeters, as the constant is then less unwieldy. The formula then becomes

$$P = 0.001,019,79 \frac{C^2}{S} \qquad (4)$$

P = grams per square centimeter.
S = square millimeters.
C = amperes.

The reason for the awkwardly small constant is that the formula involves the square of the current, which is generally a numerically very large quantity, and as the pressures are not very large numerically the constant must necessarily be very small. Calculations are therefore simplified and the constants more easily remembered by expressing the large currents C in kilo-amperes (1000 amp) instead of amperes. Formula (2) in inches and pounds then becomes

$$P = 0.022,482,5 \frac{C^2}{S^2} = \text{approximately } \frac{9\,C^2}{400\,S} \qquad (5)$$

P = pounds per square inch.
S = square inches.
C = kilo-amperes (1000 amp)

and the one in the metric system, S now being in square centimeters instead of square millimeters, becomes

$$P = 10.197,9 \frac{C^2}{S^2} = \text{approximately } \frac{10\,C^2}{S} \qquad (6)$$

P = grams per square centimeter.
S = square centimeters
C = kilo-amperes (1000 amp).

The two approximate formulas (the errors are less than 2 per cent) are now quite simple and easily remembered.

In the c.g.s. system the formula is simply

$$P = \frac{C^2}{S} \qquad (7)$$

P = dynes per square centimeter: S = square centimeters: C = current in c.g.s. units (10 amp).

Attention is here called to the fact pointed out by the writer some years ago[2] that complete rupture of a conductor can take place long before this pinch pressure has reached the hydraulic pressure at the bottom of a trough. This is due to the fact that after a certain amount of shrinking of a conductor an unstable state is reached after which further shrinkage takes place automatically and by rapidly increasing amounts, thereby causing complete rupture. This should be taken into consideration in applying the above formulas to such cases.

[2] "The Working Limit in Electrical Furnaces Due to the 'Pinch' Phenomena." *Trans.* Am. Electrochem. Soc., Vol. XV, 1909, p. 255.

Annealing of Copper and Diseases of Copper.

By F. Johnson, M.Sc.

The annealing of copper is designed to remove hardness and brittleness conferred on the metal either by cold working or by the repetition of minute stresses. Softness and toughness, which enable the metal to undergo further stresses without being dangerously embrittled, are regained.

There are many conditions to be observed during annealing, chief of which are as follows:

(1) *Correct temperature.*
(2) *Neutral or oxidizing atmosphere. An atmosphere of a reducing nature must be strictly avoided.*
(3) *Absence of foreign material from annealing furnace.*
(4) *Uniformity of heating.*
(5) *Duration of annealing.*
(6) *Method of Cooling.*

The observance of all these conditions is profoundly affected by the size, thickness and form of material which is to be annealed. Generally speaking, the thinner the material the more susceptible it is to injury by abnormal treatment.

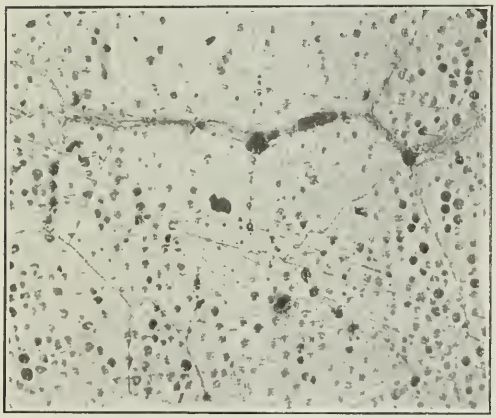

FIG. 1—WROUGHT COPPER. "BURNT" IN ANNEALING. MAGNIFICATION 100 DIAM.

(1) *Temperature.*—A bright red heat, which corresponds to about 900° C., is not too high for the purest copper. Impure copper of the refined type, if capable of being satisfactorily worked, should also easily stand this temperature.

The danger in raising copper to too high a temperature during annealing (1) lies in the occurrence of incipient fusion, but (2) is much intensified if gases of a reducing nature be present If the annealing is in the nature of a reheating preparatory to hot working, a bright-red heat may not be exceeded, for to work copper at a temperature above 1000° C. is suicidal. In the neighborhood of this temperature copper is extremely brittle and rotten, possessing neither strength nor toughness, the reason being, possibly, that the cuprous oxide eutectic assumes a pasty condition. At any rate it becomes brittle and unmalleable with an alarming abruptness, quite incommensurate with the small rise above the forging temperature.

If the annealing temperature be too low then crystalline readjustment is not complete, i. e., the hardness and brittleness due to stressing are not sufficiently removed and the material is liable to rupture if again submitted to cold work. The presence of cuprous oxide ("oxidules")* tends probably to promote recrystallization at lower temperatures than in the case of oxygen-free (deoxidized) copper.

Micrograph No. 1 shows the structure of a piece of cold-

* The author: *Journal Inst. of Metals*, Vol. IV, No. 2.

wrought copper which has been allowed to attain to too high a temperature in the annealing process, with the result that incipient fusion has been accompanied by intracrystalline oxidation causing oxidized boundaries and intracrystalline pitting.

2. *Atmosphere of Furnace.*—This should be carefully watched, as, if gases of a reducing nature, such as H, CO, CH_4, etc., all of which may be present in the products of imperfect combustion of carbonaceous fuel, are allowed to pass over copper at a red heat, or even at a lower temperature, they remove the all-important oxygen, rendering the metal porous, brittle, weak, destitute of all the properties which good copper possesses and,

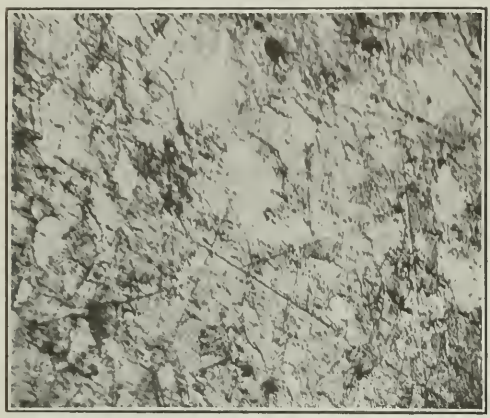

FIG. 2—WROUGHT COPPER (ARSENICAL) NORMALLY ANNEALED.

finally, amenable to no remedy short of remelting. This is commonly known as "gassing," the copper being the more sensitive to the action the higher the temperature.

3. *Foreign Material in Furnace.*—There should be no sharp grit, nor other foreign material at all on the floor of the annealing furnace, which must be kept perfectly clean. Apart from the mechanical action of such material in scratching or grooving copper, causing initial flaws which may engender failure in final tests, there is the possibility of the copper absorbing zinc from articles of brass. Brass articles should never be annealed in the same furnace and at the same time as copper articles.

Just as mercury will amalgamate with copper at ordinary temperatures, on account of the remarkable molecular fluidity and absence of viscosity of the former, so will zinc suffer a transference of its molecules to take place from the brass which contains it to copper in contact with it at a high temperature.*

So it is never advisable to calcine, in a muffle used for annealing copper, any refuse or sweepings, especially such as contain particles of brass. Otherwise the copper may take up defects, which, causing subsequent erratic behavior, may help to still further thicken that shroud of mystery which all too completely envelops the metal even now.

4. *Uniformity of Heating.*—This is of extreme importance. There are, perhaps, few works where wrough-copper material of large dimensions is annealed uniformly all over. The practice, for instance, of annealing large copper pipes over a smith's fire, bit by bit, is quite common. Where intricate shapes and sharp bends are being dealt with it is by this method impossible to insure the desirable uniformity of heating. Where furnaces are used the closed type is preferable to the open type, for, in addition to insuring uniformity of heating, all injurious gaseous products of combustion of the fuel are kept from contact with the heated metal. But whatever type of furnace is used it should be the invariable rule of the furnace man to see that every inch of metal has come to a red heat, even if it is necessary to reverse the material before withdrawal.

If this is not done the metal will vary considerably in its properties, and if it is to be put into service where, as in the case of a steam pipe, it will have to undergo the inevitable stresses due to alternate expansions and contractions, and to vibrations, it is quite certain that those parts which have been heated to the highest temperature and are, in consequence, softest, will yield most to the stresses. This localization of strains results in premature cracking and rupture of an otherwise satisfactory pipe.

5. *Duration of Annealing.*—There is no advantage in prolonging the heating beyond the attainment of a *uniform* red heat. The great danger is that the heating may be sufficient at one part and, while waiting for the remaining parts to come to the same temperature, the first part may be overheated or even "burnt."

Overheated metal, or metal which has been kept too long in the furnace, is softer than metal which has been just annealed and then withdrawn, as shown by the following figures:

Just Annealed.	*Over Annealed.*
Tensile Str. tons per sq. in.	*Tensile Str. tons per sq. in.*
15.12	14.24
See Micrograph No. 2.	See Micrograph No. 3.

Prolonged annealing induces crystalline growth and has the invariable effect of lowering the tensile strength and possibly the percentage elongation, although the latter may not be altered at all if the temperature has not exceeded a dull-red heat. Under the microscope it will be seen that the crystals have increased in size, small crystals being absorbed by larger ones.

6. *Method of Cooling.*—Copper may be quenched from a bright-red heat or cooled slowly. Quenching (1) has the effect of removing scale and retaining it in the bosh until cleaning

FIG. 3—WROUGHT COPPER (ARSENICAL) OVER-ANNEALED.

out becomes necessary. This prevents the scale, a material of considerable value, from being trodden about on the floor and lost. (2) Softens the metal and toughens it against alternating stresses. The following figures are from a paper read by Mr. J. M. Allen, January, 1909, before the N. E. C. Inst. of Engineers and Shipbuilders. The test pieces were all taken from the same sheet and were bent backward and forward by hand through 90° and over a curve of 1¼-in. radius until fractured. The figures given denote the mean number of alternations endured in two such tests:

* *The Analyst*, Vol. XXX, No. 357, Dec., 1905, L. Archbutt; also, *Journal Inst. of Metals*, Vol. III, No. 1, Bengough & Hill, p. 45.

	Sheet No.	Mean No. of times bent.	Tube No.	Mean No. of times bent.
Untreated Strips ...	S 1	36	T 1	61.5
Heated to dull red and slowly cooled.	S 10	38	T 2	92
Heated to dull red and quenched.....	S 3	39.5	T 3	99.5
Heated to bright red and slowly cooled.	S 4	43	T 4	93
Heated to bright red and quenched.....	S 11	57.5	T 11	113

Judging from these figures it would seem to be the best practice in the technique of annealing to heat to a bright-red heat and quench rapidly, thereby gaining a maximum toughness

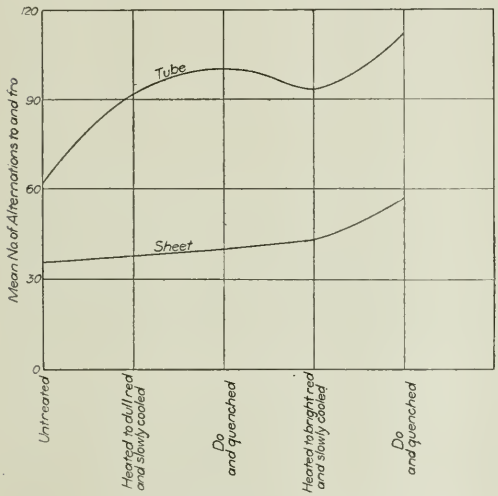

FIG. 4—EFFECT OF HEAT TREATMENT ON BEHAVIOR UNDER ALTERNATING STRESSES.

with no lowering of tensile strength or percentage elongation. The advantage of quenching seems to be the more marked (relative to slow cooling) where the copper has more lead in its composition. (As in the case of the sheet [S], see curves Fig. 4.)

Diseases of Copper.

Corrosion.

Chemical Action.—This may occur in many ways and its continuance or retardation will depend on (a) whether the product of the solvent action is protective or contributory to further wasting, (b) whether it is continuously removed so soon as formed or allowed to remain undisturbed in its protective or in its corrosive action.

In case (a) the sheet copper used for covering domes of buildings may be instanced. After exposure for some time to a marine atmosphere a coating of cupric chloride or oxychloride is formed which confers a distinct ornamental effect and is at once a protection against further atmospheric attack and an embellishment. Again, articles of copper exposed to similar action, either of sea water or other corrosive liquid, may, owing to the fact that they are in constant or intermittent motion, be continuously exposing clean surfaces to further corrosion and thus wasting gradually away.

Articles of copper exposed to a corrosive liquid and permanently removed therefrom, if not very carefully cleaned and dried, will harbor the corrosive agent in minute superficial pits or grooves and corrosion will proceed, more slowly than before and more erratically, but quite perceptibly.

Rhead ("The Corrosion of Copper and Brass," J. Inst, of Metals, Vol. 11, No. 2, p. 87) has shown that copper hardened by mechanical work is more susceptible to corrosion in acid and saline solutions than copper softened (by annealing) under similar conditions.

Sir G. Muntz (discussion on "The Failure of Non-Ferrous Metals," T. V. Hughes, Inst. of Metals, January, 1910) instanced alkaline water in boilers as the cause of intense pitting and riddling of boiler tubes.

Bengough (ibid.) stated that salt water in boilers causes corrosion on the water side of the tubes, whereas fresh water is inert, corrosion in the latter case occurring only on the fire side of the tubes. He thinks that particles of slag in the metal may form "loci" where corrosion will be first fostered, but it has yet to be proved that copper or brass tubes contain particles of slag. Even admitting the possibility of their presence in copper billets or brass castings—a possibility which is extremely remote—they would prevent the forged billet or the casting from surviving the drawing process.

Handscomb ("Characteristics of Copper under Various Conditions," Inst. Marine Engrs., September, 1909) attributes pitting in steam pipes to the ammoniacal nature of patent compounds used as heat-non-conducting coverings. In all cases of chemical corrosion the action is hastened and intensified in proportion to the temperature; the higher the temperature the more rapid the corrosion.

Galvanic Action and *Decay* have been very fully dealt with by Milton and Larke in Proc. Inst. Civil Engrs., 1903.

Gaseous Action in Course of Manufacture.—The effects of "burning," overheating and "gassing" have already been dealt with under annealing and it is extremely unlikely that wrought copper which has been seriously injured during the processes of manufacture will be allowed to issue from the works of any reputable firm of manufacturers.

Careless treatment of copper steam pipes over the coppersmith's fire may cause "gassing" of the exterior of the pipe. If only the merest superficial layer is deoxidized trouble is being brewed, for incipient cracking, even if well-nigh imperceptible, is unspeakably dangerous, since the propagation of larger cracks throughout the thickness of the pipe is thus freely encouraged and the life of the pipe assuredly shortened.

Gaseous Action (B) in Service.—Hot gases from the combustion of fuel may consist of inert gases, such as N and CO_2 and corrosive gases, such as Cl, SH_2, SO_2, COH, etc. Chlorine, sulphuretted hydrogen and sulphur dioxide must, if present in the furnace gases of a locomotive boiler, cause wastage of a serious character. They would act in the formation of a superficial layer of scale, free oxygen being probably necessary to complete the chemical equation of which an oxychloride or sulphate would be the probable product. Such a salt would be friable and non-adherent, easily shaken off by vibration or by the abrading action of cinders and dust, thus constantly exposing a fresh surface to further corrosion.

Carbon monoxide would only act on copper at a high temperature (say, incipient red) and then it would have a more than superficial effect; it would penetrate into the metal, reduce cuprous oxide present, and leave in its wake a weakened structure. It is almost certain, however, that boiler *tubes* at all events, even at the firebox end, never reach so high a temperature as to admit of the insidious inroads of reducing gases.

The abrading action of *cinders* and the "burning" action of *flame* may be noted under this head, since they are inseparable from the onward sweep of furnace gases caused by the fierce draught. Webb (Inst. C. E., 1903) showed how the red-hot cinders and ash were caused to impinge on the lower half of the boiler tube, where the latter were held into the firebox tubeplate at the ferrule, and were deflected thence in an upward direction, meeting the top half of the tube a few inches further on. The great majority of failures occurred in these two places. Cinders and flame are responsible for much of the wastage of stay-heads and "scoring" of firebox plates.

Here, too, may be mentioned the theory of local overheating (due to oil in the feed water adhering to parts of the firebox and causing a retardation of the conduction of heat to the water). Such spots would, it is thought, be subject to intense local heating, causing, on the fire side of the plate, incipient or partial fusion and subsequent weakness.

The greatest trouble experienced with circulating *water pipes* of copper is internal pitting of a local character. This has been traced in some instances to the liberation of air from the circulating water. Sea water is known to contain air in solution and if the conditions are such that the supply of water to the pipes is inconstant, they will not always be quite full, with the result that free air will be liberated, and rising to the "roof," as it were, of pipes in a horizontal position, will attack the copper under the necessarily moist, saline conditions obtaining, often in an erratic manner, causing the pipe to scale. Scale thus formed will be shaken off by vibration, and "pitting" will proceed until at length a hole is formed right through.

Ensuring that the pipes are always quite full of water has been the means of preventing further corrosion of this nature.

The presence of impurities in wrought copper may be considered as helpful, if anything, in enabling the copper to resist corrosion. Certainly the purest electrolytic copper is just as susceptible to corrosive influences as commercial "tough" copper, and possibly more so.

Swansea Technical College,
Swansea, England.

The Work of the Chemical Laboratories of the Bureau of Mines.

Dr. J. K. Clement, the physicist of the Bureau of Mines, presented an interesting paper at the recent Minneapolis meeting of the American Chemical Society on the chemical laboratory work of the Bureau of Mines.

This work is divided among a number of separate laboratories, each carrying on its own lines of work under the direction of its own chief, the whole forming a group of more or less independent units. The relation of the work of the several chemical laboratories to that of the other departments of the bureau varies with individual cases. In general, however, the problems of the chemists are closely connected with those of the mining and mechanical engineers.

The fuel testing laboratory is occupied mainly with the analysis and calorimetric testing of fuels, including coal, coke, lignite and peat. In addition to analyzing samples of all fuels used in the boiler and gas producer tests of the bureau, ultimate analyses and calorific value determinations are made on mine samples of coal collected at various places. The data on these latter tests are of value in establishing the composition and heating value of the coals in connection with the classification of the coal fields of the United States.

In addition to the laboratory at Pittsburgh, there is located in Washington, D. C., a laboratory in which are tested samples of coal, delivered to the various buildings, arsenals, navy yards and military posts within the District of Columbia and in various parts of the country, and of the coal purchased by the Panama Railroad.

Fusibilty and Clinkering of Coal Ash.—In the use of coal under steam boilers, the property next in importance to its calorific value is perhaps the fusibility of its ash. Indeed, some coals, which have a high heating value, are worthless for making steam on account of their tendency to clinker and adhere to the grate bars. The relation between the fusibility and clinkering properties of coal ash and its chemical and mineralogical composition is now being investigated.

It is interesting to note that TiO_2 was found in all the clinkers examined in amounts varying from 1 per cent to 3 per cent. Determinations of the fusion point of various ashes give values ranging from 1150° C. to 1400° C.

Chemistry of Petroleum Technology.—The bureau is making a study of the commercial bodies contained in the crude petroleums of the United States; of the methods for their separation and purification and of their economic uses. The California fields, because of their showing at this time the greater promise of a large and continued production, their promixity to naval stations and the peculiar adaptability of their product as a maritime and a locomotive fuel, have been selected for first study. Besides the determination of the properties and uses of the various products of the petroleums of the country, an investigation is being made of the processes of distillation and of the methods of refining.

Combustion Investigations.—The processes of combustion in the boiler furnaces are being investigated in a furnace specially designed for the purpose. By taking simultaneous samples of the combustion gases, the progress of the reactions may be followed and the time or space necessary for the complete combustion of various coals and under varying conditions of operation may be determined.

The process of producer gas formation is being studied from a physico-chemical standpoint, and an attempt will be made to apply on a commercial scale the results of laboratory experiments on the rate of formation of carbon monoxide and water gas.

The Composition of Coal.—Our scientific knowledge of the chemical character of coal is limited almost entirely to its chemical analysis and its adaptation to certain industrial operations. The object of one of the investigations of the bureau is the isolation and identification of some of the constituents of coal. By the use of inert solvents it has been found possible to extract as much as 35 per cent of the original coal. A number of different substances have been isolated and the analysis and molecular weights of some of these substances have been determined. In a few cases it is believed that the materials are practically pure substances.

The Volatile Matter of Coal.—The quantity and composition of the gases evolved from various coals, when heated to temperatures of from 400° to 1000° C., have been determined. In the experiments which are now in progress particular attention will be given to the influence of the rate of heating on the character of the gases produced; to the initial composition of the gases at the instant of liberation and to the thermal decomposition of these gases during passage over heated surfaces.

Weathering and Deterioration of Coal.—In co-operation with the Navy Department, the Panama Railroad Company and the University of Michigan, the Bureau is conducting an extensive series of tests on the deterioration of various coals in storage both in the open air and when submerged in fresh water and sea water.

The Accumulation of Gas from Coal.—The quantity and rate of formation of inflammable gas from freshly mined coal, at ordinary temperatures, and the rate of absorption of oxygen by the coal have been determined.

The Spontaneous Combustion of Coal is being investigated by the Bureau. Statistical information will be combined with the results obtained in the laboratory.

The Burning of Coal in Mines under a Diminished Supply of Oxygen.—The factors governing the propagation or extinguishing of fires in mines are being investigated. Chief among these are variations in temperature and in the oxygen content of the surrounding atmosphere.

Examination of Mine Gases.—Examination is made of samples from normal mine air, from the after-damp following explosions, from stagnant areas and from burning areas during mine fires. Particular attention has been given to the detection of small amounts of carbon monoxide. By analyzing samples during the progress of mine fires, the chemist has assisted in combating fires. The effect of variations of barometric pressure on the exudation of methane and the influence of carbon dioxide on the explosibility of mine gases are being investigated.

The Chemistry of Explosives.—Chemical analyses are made of all explosives submitted to the Bureau for test, of the products of combustion of explosives and of electric detonators, blasting caps and fuses. All explosives, blasting caps, electric detonators and fuses purchased by the Isthmian Canal Commission are inspected by representatives of the Bureau, and all shipments of such explosives are sampled and analyzed.

Coal Dust Explosions.—The two greatest sources of danger encountered in mining operations are the explosive gases given off by the coal, and the finely divided coal dust which exists throughout most coal mines. The first danger can be overcome by increasing the ventilation in the mines. Unfortunately, this increases the danger from the coal dust by the removal of its moisture.

A laboratory method has been devised to test the inflammable character of samples of coal dust, and to classify them according to their inflammability. This method is based on determining the amount of combustion which takes place when clouds of dust of the same density are ignited under the same conditions, the amount of combustion being determined by the pressure developed within the explosion vessel. In this way it is possible to obtain results on any one sample of coal dust which agree to 3-5 per cent of the total pressure developed.

One of the proposed means of lessening the inflammable character of coal dust is to add a non-inflammable dust. The laboratory method used to investigate the inflammability of coal dust has been extended to various percentages of coal dust and finely ground shale in order to determine to what extent the combustion is limited by the presence of the inert dust. The experiments indicate that a marked diminution of pressure is not obtained until about 25 per cent of inert dust is added, the pressure then falling off rapidly with a further increase in the amount of shale dust added.

Western Chemists and Metallurgists Disband.

The Western Association of Technical Chemists and Metallurgists, which was organized in Denver, Col., six years ago, has taken the necessary steps to dissolve the incorporation and disband. The association was formed to promote the interests of Western men engaged in chemistry and metallurgy of the non-ferrous metals and has unquestionably supplied a need that was not met by any other society in the United States.

The conduct of the affairs of the association has never been an easy task, for the Western country is large, its centers of industry few and far between, and the men in position to give time and attention to the work are widely scattered. Further, concerted action often has been difficult by reason of the itinerant character of a large proportion of the membership.

The association has published six volumes of a creditable journal, which has been the most difficult feature to maintain, and without which it would have been impossible to have attracted or held a membership. It is with considerable regret that the board of control has taken steps toward disbandment, but the action was taken only after securing an expression of opinion from the members, whereby it was concluded unwise to enter on a new year with poor prospects of a successful finish.

The Utah Society of Engineers conducted an excursion over the lines of the interurban roads recently put into commission between Salt Lake City and Brigam City, Utah, on Saturday, Nov. 26. Stops were made to inspect power plants at Willard, Ogden Canyon and Lagoon; to see the concrete-lined Weber-Davis canal and to view other engineering works of interest. This is the second regular inspection trip made this season, the first having been to the new smelter of the International Smelting & Refining Company at Tooele, Utah, on Oct. 29.

Zinc Ore-Dressing in Colorado—IV.

By H. C. Parmelee.

Magnetic Separation.

The presence of much iron sulphide in zinciferous ores necessitates the adoption of different treatment than in the case of ores practically free from such mineral. Wet dressing alone is insufficient for the separation of the iron from the zinc on account of the slight difference in specific gravity, that of blende being about 4, and of pyrite 5. If galena also is present it may be separated by the usual wet methods, its specific gravity being 7.5.

In case all three of these minerals are present two courses are open. By preliminary wet dressing the lead may be removed as a clean concentrate and a zinc-iron middling made for further treatment by magnetic or electrostatic processes; or the treatment may be reversed, the iron being removed by magnetic separation and the zinc-lead product finally separated on tables. Electrostatic separation of iron and zinc is effected without preliminary roasting, and for the details and principles of this process the reader is referred to our issue of November, 1910 (Vol. VIII, No. 11, page 636).

Magnetic separation of blende and pyrite may be accomplished without preliminary roasting by the use of high intensity

WILSON MILL, ROBINSON, COL.

magnetic separators of the Wetherill type, the zinc mineral being lifted out of the mass. But the more usual procedure is to give the ore a magnetic or "flash" roast, rendering the iron magnetic, after which it is separated from the mass by separators of the low-intensity type, such as the Dings. Manifestly the choice of machines and method of procedure depends largely on local conditions and must be determined by experiment. In Colorado both types of machines and methods of practice are employed, although the prevalent method is roasting and magnetic separation, followed by wet dressing.

The object of the roast is to convert certain non-magnetic minerals into magnetic substances so that they may be separated by means of a magnet properly applied. The conditions required for successful work are very precise and need considerable care. Either magnetic sulphide, Fe_3S_4, or magnetic oxide, Fe_3O_4, may be produced, but some experiments have shown[1] that in an ore containing pyrite, blende and galena the magnetic concentrate runs lower in lead and zinc when magnetic sulphide is produced than when magnetic oxide is the

[1] G. M. Gouyard. *Proceedings Colorado Scientific Society.*

product of the roast. Furthermore, the production of magnetic sulphide is a simpler procedure than roasting to magnetic oxide, the latter usually requiring the addition of carbonaceous material to reduce ferric oxide to magnetic oxide.

Siderite often occurs in zinc-lead-iron ores, and in the calcination process it is converted into magnetic oxide under much the same conditions which convert pyrite into magnetic sulphide. Less time and slightly higher temperature are required for the conversion of the siderite than of pyrite, but an

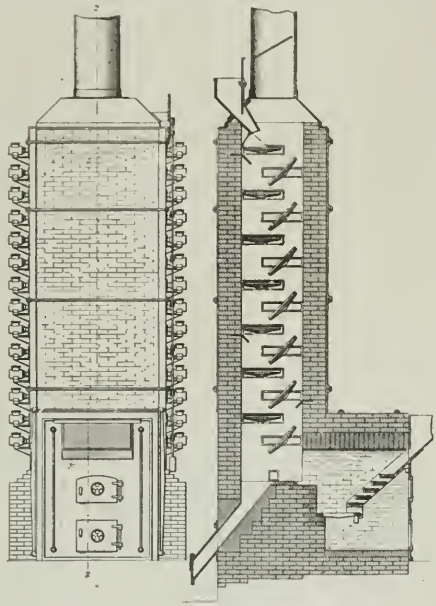

FIG. 1.—FAIRCHILD ORE DRYER, FRONT ELEVATION AND SECTION ON LINE 2-2 OF FRONT ELEVATION.

ore containing both may be treated successfully, although the same degree of conversion of both minerals can hardly be obtained. Ore properly roasted for magnetic separation will be recognized by its uniform black color and the absence of the reddish tinge which indicates oxidation. Blende will be coated with a thin layer of oxide. When these conditions are attained a magnet of low m.m.f. will remove the iron readily.

The Wilson Mining Company.

The mines and mill of the Wilson Mining Company are situated near Robinson, Summit County, Colorado. The ore is a mixed zinc-lead-iron sulphide, with some siderite, in a silicious gangue. The average composition is: SiO_2, 11 per cent; Fe, 23.6 per cent; Pb, 10.4 per cent; Zn, 14.8 per cent; CaO, 4 per cent; S, 35.6 per cent; Ag, 7 oz. per ton, and Au, 0.07 oz.

The mill has a daily capacity of 125 tons according to its present roaster equipment. The principal steps in the process are crushing and grinding, drying, roasting, magnetic separating and wet dressing. The mill is conveniently divided into units, each with ample bin room in which to store its finished product ready for treatment in the succeeding unit, thus making the operation of each unit independent of every other.

Crushing Unit.

There are no crude ore bins at the head of the mill, but ore is trammed from the mine directly to the crushing unit, where it is dumped over a grizzly (1¼-in. openings) to a Symons No. 5C gyratory crusher, reducing to about 2½-in. size. This machine is much more compact than the usual type of gyratory, and differs further in having a stationary central shaft around which revolves an eccentric imparting the crushing force to the head. Automatic circulation of lubricating oil is provided by a pump, chain-driven from the pinion shaft. About 5 gal. of oil per minute are pumped to the top of the central shaft, where the stream is divided, half passing downward between the stationary shaft and rotating eccentric sleeve and half between the sleeve and crushing head. The oil collects in a basin in which the gear is housed and is returned by gravity to the pump.

The crushed ore and undersize of the grizzly are combined and discharged by belt conveyor over a revolving electromagnet contained in the pulley of the conveyor, for the purpose of removing pieces of iron and steel which accidentally find their way into the mill feed. The ore is then sized for a second crushing by passing over a shaking launder, 12 ft. x 3 ft., having a perforated area of 1-in. holes near its discharge end. The oversize is crushed to about 1-in. size in a Symons gyratory No. 3C.

A 14-in. B. and B. elevator then raises the crushed ore to a ¼-in. mesh trommel screen, the oversize of which is returned

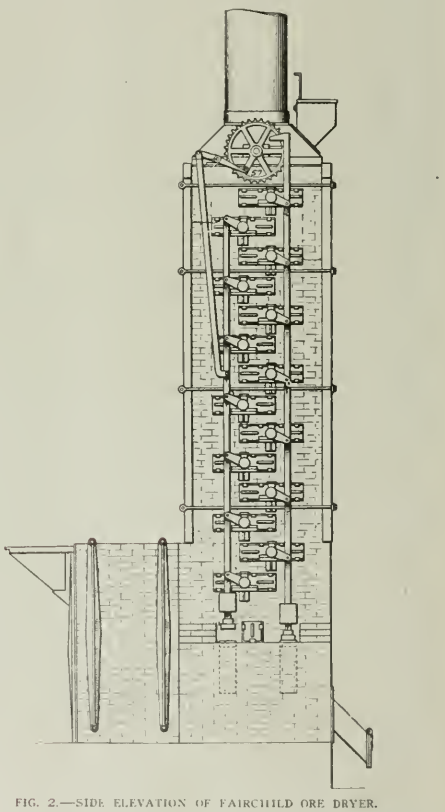

FIG. 2.—SIDE ELEVATION OF FAIRCHILD ORE DRYER.

to a set of 14 x 27 rolls set ⅜ in. apart. The roll product is returned to elevator and screen. The screen undersize, which is the finished product of this unit, flows to a point over the center of a rectangular ore bin of 1000 tons capacity, to which it is distributed by a belt running lengthwise of the bin. The belt and frame on which it moves is half the length of the bin and is operated by a reversible motor, so that ore falling onto the distributor may be dropped into the bin from

either end of the belt. The entire distributing mechanism also may be shifted by means of the same motor to occupy any position on a track extending the length of the bin. In this way ore may be conveniently distributed to any desired point.

Drying and Grinding Unit.

The crushed ore bin is provided with eight discharge gates through which ore is drawn for treatment in this unit. The gates are of the rack and pinion type, provided with a belt-driven plunger feeder. Ore thus discharged from any number of gates falls onto a belt conveyor running the length of the bin just below the gates. This manner of drawing the crushed ore from the bin insures a uniform feed for the succeeding unit, as regards size and contents.

The ore is elevated to the dryer, which is of novel construction, designed by Mr. O. H. Fairchild, superintendent of the mill. It is illustrated by drawings in Figs. 1, 2 and 3. It consists of a vertical brick chamber, about 20 ft. high and 5 ft. x 8 ft. in its other dimensions. Within the chamber are two sets of

FIG. 3—ORE DRYER, WILSON MILL.

pans so arranged and operated that each set alternately dumps its contents onto the other. As the pans of one set are staggered vertically with reference to those of the other it will be seen that ore fed onto the uppermost pan makes its progress through the dryer by a series of intermittent discharges from pan to pan. This exposes new surfaces of ore to the hot gases ascending from the fire box in the base of the chamber and thus effects the drying in a short time. There are seven pans in each set. Ore is discharged from one set to the other every 15 seconds, so that it requires 3½ minutes for ore to pass through the dryer. Ore is delivered by elevator to the hopper shown in the top of the chamber. The feed is continuous, but the pans dump when a charge of about 75 lb. has been received, giving the dryer a capacity of about nine tons per hour. The fuel consumption is about 7 lb. to 8 lb. of coal per ton of ore dried. Cost of fuel, $4.75 per ton.

From the foot of the dryer the dry ore is conveyed by traveling plow conveyor through a metal launder to the elevator which feeds a 6-mesh trommel screen. The oversize is returned to a set of 14 x 27 rolls and thence again to the elevator and screen. The undersize passes to a second trommel fitted with 10-mesh screen, the oversize of which is returned to a second set of rolls similar to the first and thence to the elevator and 10-mesh screen. The 10-mesh undersize is the finished product of this unit and is sent by belt conveyor to the dry ore bins of 275 tons capacity.

Roasting Unit.

From the dry ore bins the ore is elevated to an oscillating plow conveyor placed above the roasters, which are arranged in two rows, one on either side of the conveyor. The ore is discharged into feed hoppers on each furnace, to which it is finally fed by plunger feeders.

There are five roasting furnaces of the circular multiple-

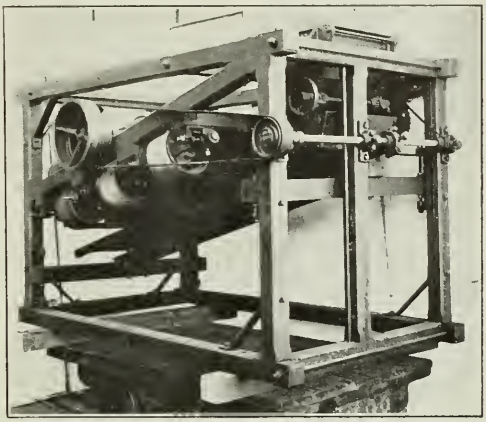

FIG. 4—FAIRCHILD MAGNETIC SEPARATOR.

hearth type, locally known as the Dewey roaster. Each furnace has six hearths, 14 ft. in diameter. A vertical central shaft driven from beneath the furnace carries the stirring arms, of which there are two, diametrically placed in each hearth. Ore is fed at the periphery of the upper hearth and plowed to the center, where it falls onto the next lower hearth and is plowed to the periphery, falling to the third, and so on through the furnace. The rabble arms make one revolution in 20 seconds, and the time required for the passage of ore through the

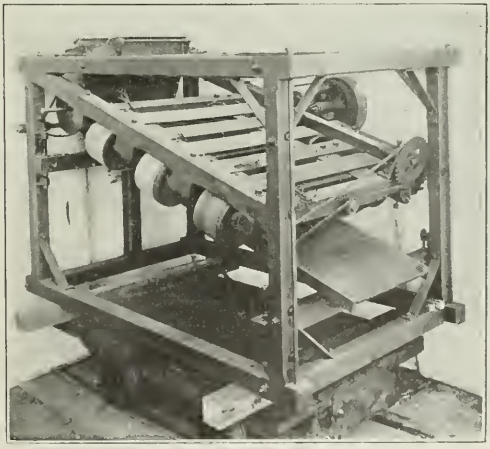

FIG. 5—REAR VIEW OF FAIRCHILD MAGNETIC SEPARATOR.

furnace is about two hours. The capacity of the furnace is 24 tons in 24 hours, making a total capacity of about 125 tons per day, which determines the present capacity of the mill.

The temperature of the three lower hearths of each furnace is indicated by Bristol electric pyrometers. An average tem-

perature of 1100° Fahr. to 1150° Fahr. is maintained, although the furnace attendant is not wholly guided by the pyrometer indication. The appearance of the ore on the lower hearth is a good guide to an experienced man, and this is often accepted in preference to the pyrometer reading and regulation made accordingly. The temperature is usually a good guide to successful roasting for magnetic separation, but changes in the physical condition or chemical composition of the ore are such that two furnaces apparently receiving the same feed may have to be run at different temperatures in order to get equally good results in the following magnetic treatment.

Furnaces of the type described are usually preferred for magnetic roasting on account of their low cost of installation, maintenance and operation, and the fact that they require less space than revolving cylinders. Considerable dust is made, and at the Wilson mill the roasters are provided with dust catchers. The roaster gas passes from the furnace through a down-take into a cylindrical iron chamber with conical top and bottom. The gas enters the settler practically tangent to its periphery so that a downward swirling motion is imparted to it. The dust particles settle into the conical bottom and the gas rises and is discharged into the air. As the roasting of the dust particles is practically completed they are returned to the lower hearth of the furnace and mixed with the discharging ore.

The roasted ore is cooled in a revolving drum, 39 ft. x 3 ft., set at a pitch of 1 in. to the foot, and making about 4 r.p.m. Cooling water is discharged over the drum from a launder placed above it. The cooled ore is elevated to an Edison 10-mesh screen for the purpose of removing the small quantity of oversize which results from the fritting together of particles in the furnaces. The oversize of the screen is reground in a set of small rolls and returned to the elevator and screen. The screened ore is then conveyed by a traveling plow conveyor to bins of 500 tons capacity.

Magnetic Separating and Wet Dressing Unit.

The magnetic separators, which also are designed by Mr. Fairchild, are placed just below the roasted ore bins, and receive a continuous feed through spouts leading to their feed hoppers. The machine is illustrated in Figs. 4 and 5. There are three sets of electromagnets, the second and third being of higher intensity than the one immediately preceding it. The voltage is 110, and the amperage 1.5, 3 and 6 for the first, second and third magnets respectively.

Each set is composed of 10 electromagnets of alternately reversed polarity, this being the principal feature of the machine. The magnets are arranged transversely to the shaking tray, and a belt travels around each set for the purpose of removing the magnetic concentrate from the machine. Ore is brought into the magnetic fields on an inclined shaking brass tray, on the under side of which are three bars of iron so placed as to be beneath the magnets. Passing under the first set of magnets the strongly magnetic particles of ore are attracted to the cross belt and removed from the machine. The same operation is performed by the second and third sets, where the weaker magnetic particles are attracted by the stronger magnets.

The object of alternating the polarity of adjacent magnets is to obtain a cleaner separation. In the process of magnetic separation it happens that more or less non-magnetic material, mineral and gangue is removed with the magnetic concentrate by being mechanically entangled with it. By alternating the polarity of the adjacent magnets in each set the particles attracted to the cross belt are caused to change position as they pass underneath the successive magnets, thereby offering the greatest opportunity for mechanically entrained matter to drop out of the mass.

At the Wilson mill there are five of these separators, each having capacity to handle the ore from one roaster. The shaking tray oscillates 325 times per minute. The cross belts have a speed of 350 ft. per minute. The power required for the mechanical operation of a machine is about ¼ hp.

The magnetic concentrate is removed by belt conveyors running beneath the floor of the separator room and finally delivered to storage bins. This product is useful as fluxing material for lead smelters, and valuable also for the small quantity of lead, silver and gold contained.

The zinc-lead-silica mixture is also conveyed from the magnetic machines by a system of belts to a central elevator which raises it to a point above the concentrating tables, where water is added and the pulp prepared for concentration. The pulp is mixed by a screw revolving in a launder, water being introduced at about the middle point of the latter. From the mixer the pulp flows into a box which provides for the immediate elimination of some slime by overflow. The heavy pulp is then classified in a pocket classifier, the pockets being conveniently arranged at points in a launder extending above the tables. Hydraulic water is introduced by means of a pipe entering the side of the pocket and standing vertically in it. The pipe is capped at the top and water is discharged through three annular series of holes drilled in the pipe. The first series is 1 in. below the cap and each of the others is arranged 3 in. below the one above it. Just above each set of holes an annular apron is attached to the pipe to spread the flow and provide a uniform rising current of water in the sorting column. The last two pockets are dewatering boxes with clear overflow and slime underflow, which is combined with the first slime for concentration.

The table equipment comprises nine Wilfley and two Card tables, one of the latter being a special slime table. Eight of the tables are used for direct treatment, and three for retreatment of middling. The two Card tables are used for the finest sizes, one on direct concentration and the other on retreatment of middling. The products are lead concentrate, zinc concentrate and tailing; the concentrates are laundered to filter bins of the usual type and the tailing to waste.

Products and Sampling.

The following analyses of concentrates represent average shipments:

Magnetic Iron: SiO_2, 6.5 per cent; Fe, 46 per cent; Zn, 3 per cent; Pb, 2.2 per cent; Au, 0.05 oz. per ton, and Ag, 4.5 oz.

Zinc: SiO_2, 7 per cent; Zn, 41 per cent to 42 per cent; Fe, 11 per cent; Pb, 6 per cent; Ag, 8 oz. per ton.

Lead: Pb, 67 per cent; Zn, 6 per cent; Ag, 34 oz. to 38 oz. per ton.

The tailing carries about 9 per cent zinc and 1.2 per cent lead and amounts to 15 per cent to 18 per cent of the ore treated.

Provision is made for automatic sampling of the crude ore and tailing. The former is sampled just above the crude ore bins after it has been screened through the ¼-in. mesh trommel. The sample represents 5 per cent of the ore. The tailing sample represents 1/230 of the pulp, and provision is made for collecting a separate sample for each eight-hour shift. The tailing sampler is a horizontal wheel with vanes on its periphery, against which the stream of pulp flows, causing the wheel to revolve. At one point on the periphery of the wheel is a ½-in. slot which receives a portion of the stream and conducts it to the sample boxes. The slot bear a ratio to the periphery of the wheel of 1:230.

Power, Water and Labor.

The mill is electrically operated throughout, power being received from the Central Colorado Power Company at 10,000 volts and transformed to 440 volts. The distribution of motors is as follows:

Crushing Unit: For crushers, rolls, elevator and screen, 75-hp motor; maximum demand, 43 hp. For distributing ore to bins, 2-hp motor.

Drying and Grinding Unit: For dryer, rolls, elevators, screens and conveyor, 75-hp motor; maximum demand, 32 hp.

Roasting Units: For roasters, cooler and elevator, 25-hp motor; maximum demand, 14.5 hp; on cooler only, 6 hp. For conveyor and elevator, 25-hp motor; maximum demand, 9.6 hp.

Concentrating Unit: Motor generator, 10 hp; maximum demand, 11.2 hp. For tables, conveyors, etc., 25-hp motor; maximum demand, 17.7 hp; or with centrifugal pump, 23.7 hp.

The water supply is from Ten Mile Creek, and is pumped by an electric driven duplex piston pump to a 50,000-gal. storage tank 180 ft. above the creek. This pump is operated by a 15-hp motor. The pumping station is also equipped with a centrifugal pump operated by a 50-hp motor. Some of the mill water is reused, viz., that from the concentrate bins. The bins are constructed so that the filtered water is laundered to a sump, from which it is returned to tanks in the mill by a centrifugal pump having a capacity of 180 gal. per minute and operated by the motor running the tables.

The labor required in the operation of the mill is five men per eight-hour shift when crushing is done, which is usually but one shift per day. On the other two shifts only four men are needed; one for the dryer and rolls, one for roasters and separators, one for tables and a shift boss.

The Wilson mill is the latest in Colorado to apply successfully the process of magnetic separation to complex sulphide ore. The foregoing analyses of the products attest the quality of the work, and it will not be long until the plant is working at full capacity. Acknowledgment is due Mr. O. H. Fairchild, general manager of the company, for the data and information.

Magnetic Specimen-Holder for Microscope.

A specimen-holder for microscopes, particularly a magnetic holder for metallic specimens used under a high-power instrument, has recently been patented by Prof. ALBERT SAUVEUR, of Harvard University. In order to properly examine a piece of metal it is necessary that the surface be held at a plane accurately perpendicular to the optical axis of the instrument. While it is possible to prepare a specimen with two parallel sides the operation is a difficult one, and this difficulty is overcome by Dr. Sauveur by the arrangement shown in the adjoining illustrations, reproduced from his patent (977,842, Dec. 6, 1910).

Fig. 1 is a plan view of the mechanical stage of a high-power microscope equipped with the magnetic holder and showing a specimen in place, Fig. 2 is a plan view of Dr. Sauveur's magnetic specimen slide with a specimen slightly removed therefrom, and Fig. 3 is a central sectional view showing the specimen in place beneath the slide.

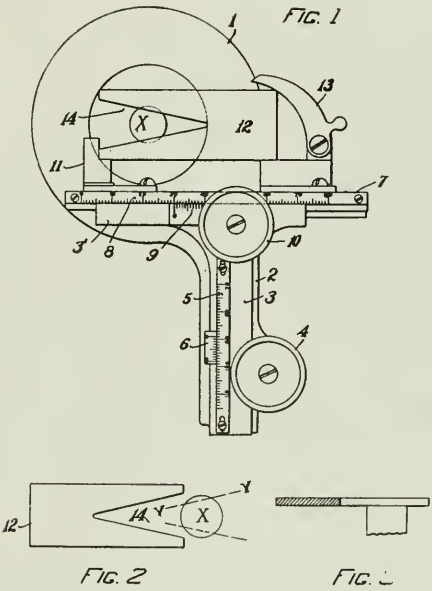
The circular stage 1 is provided with a lateral bracket 2 upon which is mounted a slide 3, being controlled by the milled wheel 4. The scale 5 reads on the vernier 6. The slide 3 carries a cross slide 7 having a scale 8 reading on a vernier 9 and controlled by a milled knob 10. On the cross slide 7 is a stop 11, having a right-angled notch, within which one edge of the magnetic specimen slide 12 may rest. The spring arm 13 bears against the corner of the slide diagonally opposite from that first mentioned, so that the slide is always clamped in exactly the same position.

The slide 12 is cut with a V-shaped opening 14, so that specimens of varying sizes may be held under it. As it is frequently necessary to re-examine a specimen at exactly the point first observed, Dr. Sauveur finds that this V-shaped opening affords the possibility for the following practice. A specimen, as indicated by X, is placed under the slide 12 in any convenient position where it has sufficient bearing to be held firmly by the magnetism of the slide and the operator then scratches on the plain surface of the specimen a pair of converging lines Y—Y, which will indicate the exact position on the V-notch 14 which the specimen is to occupy. The position will, therefore, be readily replaced at any time upon the slide and may be brought by the scale readings back to its proper position under the objective.

The Adhesion of Electrodeposited Silver in Relation to the Nature of the German Silver Basis Metal.*

BY ANDREW MCWILLIAM AND W. R. BARCLAY.

A few years ago the authors had their attention specially drawn to a rather serious trouble in connection with the behavior of high-quality electroplated spoons and forks under very severe conditions of wear. It is well known that at the present day a much larger proportion of such goods made are used in hotels, in steamboats and by caterers than formerly. Owing chiefly to the necessities of the case, but partly to the



FIGS. 1 TO 3.—MAGNETIC SPECIMEN-HOLDER FOR MICROSCOPE.

destructive instincts of virile humanity, these goods are subject to very much severer trials than they would have undergone had they found their way into use in the service of private families. For in hotels spoons and forks may have to be gathered up in large baskets and thrown into the receptacle in which they are to be washed, a kind of treatment that must be remembered in considering what follows.

A large quantity of spoons and forks, manufactured presumably under the best commercial conditions, examined and passed by experienced observers before being sent out from the factory, and apparently only differing from ordinary products in having an exceptionally heavy deposit of silver, were, after actual usage for eighteen months or so, returned to the makers with the complaint that the deposited silver coating was "peeling" or "stripping" along the edges and from parts of the surfaces of the articles.

As the trouble was not confined to a few isolated pieces, but extended to the majority of the articles in a consignment, and was also in time found to occur in connection with goods from different firms, it was felt that the matter warranted a thorough investigation, particularly as no specific fault could be traced in any of the processes through which these goods had passed, where the details of the processes could be known.

In order to correct a misapprehension which might arise, it may be necessary to point out that no attempt is here made

*A paper presented before the Institute of Metals at the January, 1911, meeting.

to discuss the ordinary causes of the "stripping" or "peeling" or "blistering" (as it is sometimes called) of electrodeposited silver from the basis metal during processes of manufacture, such, for instance, as that due to inefficient cleaning from grease or from oxide, careless treatment in scratch-brushing, or in the general preparatory stages of treatment, unsuitable plating liquid, etc., because articles so treated rarely pass from the hands of reputable manufacturers, the faults being revealed during the subsequent finishing and burnishing processes, it being well-known that if the slightest trace of grease or oxide remain on the surface of the basis metal the electrodeposited silver will blister under the pressure of the steel burnishing tools used in finishing.

The investigations were conducted from an entirely different point of view, the authors being convinced that the stripping of silver from articles which had passed all the ordinary tests of the manufacturer, and had indeed been in the hands of the users for periods varying from six months to two years, could hardly be ascribed to any of the ordinary causes mentioned.

From general experience and from the examination of many plated articles that had been a generation in wear the authors had formed the opinion that the adhesion had something to do with the nature of the basis metal, hence the investigations described in the present paper were undertaken with the view of determining not only the nature of the adhesion of electrodeposited silver to the alloys known commercially as German silver or nickel silver as a basis metal, but also to find out what difference, if any, exists between the various grades of German silver in general use in the trade, as to their suitability to form a basis metal for heavily electroplated articles which are liable to receive rough usage.

(A) Samples Tested.

The earlier experiments were made on a number of spoons and forks of various sizes supplied by manufacturers, and of the grades known in trade circles as firsts, seconds, thirds and fifths. Analyses of these were not made, but the makers reported them as having approximately the following compositions as to nickel: Firsts, 20 per cent; seconds, 16 per cent; thirds, 12 per cent; fifths, 7 per cent. The content of copper appeared to vary between 56 and 59 per cent, according to the few assays made.

In addition to these spoons and forks several test strips were obtained of each of the grades described, and of a similar character to spoon and fork blanks. All the pieces were treated so far as possible in exactly the same manner, and cleaned, prepared and electro-silverplated, according to the best methods in general use, with the one exception that a few of the samples were given a preliminary coating of copper before silverplating. The silver deposits given to these were equal to the highest qualities for high-class work, and the electroplating was done by experienced workers, under the ordinary conditions of works practice. The experiments on the above pieces were carried out several years ago, and samples were electroplated in different works. Those which will now be described have been made under the personal supervision of the authors during the last twelve months, as, in order further to test the matter, in view of the possible publication of results, they determined to prepare a series of nickel-silver alloys corresponding approximately to those in ordinary use among electroplate manufacturers.

The following table gives the compositions of the alloys accordingly made

Table I.

Marks.	Nickel. Per Cent.	Copper Per Cent.	Zinc. Per Cent.
A	20	57	23
B	18	57	25
C	16	57	27
D	14	57	29
E	12	57	31
F	10	57	33
G	8	57	35
BZ	18	50	32
BC	18	64	18

The choice of the above alloys is largely empirical, but they are fairly representative of the usual grades of copper-zinc-nickel alloys in commercial use. An endeavor has been made to systematize the series by fixing the proportion of copper on the uniform basis of 57 per cent throughout, with the exception of the last two members, BZ, in which 7 per cent of the copper is replaced by zinc, and BC, in which 7 per cent of zinc is replaced by copper.

Each alloy has been made under the ordinary conditions of works practice, manganese being used as a deoxidizing agent. The metal was cast into ingots of about 18 lbs. weight. These were rolled into sheets of a thickness and width suitable for spoon and fork blanks, and cut up into strips each 8 inches long and varying from ½ in. to 1 in. in width.

In every respect these strips correspond to spoons or forks with the exception that they have not undergone the process of stamping. A few odd strips from some members of the series have been made into forks, and these have been submitted to tests in the same way as the blank strips.

The electro-silverplating of these strips has been done under the best commercial conditions of manufacture, in an electroplating shop through which large quantities of spoons and forks are daily passing. They have been prepared for the depositing vat with due care and with all the precautions which would be taken by any careful electroplater to ensure the best adhesion of the silver deposit, but they were not subjected to exceptional treatment.

The electroplating solution used was the usual standard one of the double cyanide of silver and potassium, and the weight of silver deposited on each strip was at least equal to that given to the highest qualities of spoons and forks and to those previously described.

Table II gives the weight of deposit on the strips of each alloy, calculated per square inch of the surface.

Table II.

Marks	Deposit per Square Inch in Ounces Troy.
A	0.0196
B	0.016
C	0.0215
D	0.021
E	0.017
F	0.024
G	0.024
BZ	0.0198

The slight variation in the weight of deposit is explained by the fact that it was considered advisable to give each strip a minimum deposit at least of the quality indicated above, without in any way interrupting the course of deposition, such as by taking the specimens out of the vat for intermediate scratch-brushing, a practice often followed in the making of very heavy deposits in order to keep the coating as smooth as possible. The strips were consequently in the vat during the greater part of the working day, and naturally the rate of deposition varied as more or less work passed through the vat in the course of the day's operations.

(B) Tests Applied.

The guiding principle in designing tests for the purpose of the investigation was to subject the samples to strains such that the basis metal and its silver coating would be given, if possible, a certain amount of movement relative to one another, and in addition that the coating itself should be fractured. In all the cases of stripping of which mention has been made in the introduction the stages of development of the fault have appeared to be, first, that along the edges of the spoons or

forks concerned the silver deposit has in course of severe wear become broken or cut through, then these broken edges have gradually curled or peeled up, and if the deposited silver is thick, and therefore of sufficient substance, it may readily be pulled away from the basis metal surfaces. In some cases it has been possible by care and patience to peel the silver coating away from the fork almost from one end to the other.

With these points in view several preliminary tests were made with the apparatus available, and finally it was decided to adopt the test which had first appealed to the authors.

FIG. 1. PHOTOMICROGRAPH OF FIRST-GRADE GERMAN SILVER TEST-PIECE, COPPERED AND SILVER-PLATED. MAGN. 140 DIAM.

namely, a simple cold bending test. One part of the sample is gripped in a vise and the free part is bent to and fro until it breaks off. It is advisable that the angle of the bend should be about a right angle, in order to insure that the deposit and the basis metal get sufficient movement relative to one another.

It will be evident that this test is an extremely severe one, and that unless the metals are holding together almost as one the silver must be parted from its base, for the silver on the outside of the bend must move a greater distance than the basis metal, and on the inside of the return bend a less distance.

In view of the results it should be noted also that the order of increasing ductility of the metals being as a rule from the high-percentage nickel alloys to the low ones, the latter bearing more bending before fracture than the former, the test is more severe for metals of the G, F and E types than for A and B. In practically every case the samples were tested to destruction.

In addition to the mechanical tests applied representative sections were cut from each series for microscopical examination.

(C) Results of the Tests.

In the case of all the samples of the third and fifth grades and of the G, F and E specimens of the special alloys in Table I, it has been exceedingly difficult to peel up the silver coating in any way. In some few cases just at the point of fracture it has been possible to raise the silver coating very slightly at the top, but, in endeavoring to strip it further, the silver, though very tenacious and ductile, has broken rather than leave its base. It has, indeed, repeatedly surprised the authors to find how extremely adherent the coating is even under the severest tests.

Test pieces of first and second grades and of A and B of Table I, however, behave in a very different manner. In practically every instance the silver coating left the base at the point of fracture, and in a large majority of instances it could be pulled away quite readily from a considerable part of the surface without breaking the silver. In the cases of C and D evidence of imperfect adhesion was not so pronounced as in A and B, still the authors do not regard these as so good as E, F and G.

In the earlier experiments described a few samples of first and second grades were given rather a different treatment; they were prepared for plating in the ordinary manner, but before silver was deposited on them they were given a thin coating of copper from an alkaline copper solution, then transferred to the silver vat and given a heavy deposit of silver. These samples were then put through the same tests as the previous ones, and again there was obtained evidence of imperfect adhesion, though not quite to the same extent as formerly. The adhesion even in these cases was not to be compared, however, with that obtained with the lower-percentage nickel alloys G, F and E.

The electrodeposited silver in all the cases was tough and strong.

In order to carry the matter still further the authors quite recently obtained from another firm of German silver manufacturers a few spoons and forks of first and second grades, and the results given by these pieces when plated and tested are in every way confirmatory of the foregoing results.

A considerable number of test-pieces after plating and before being submitted to the bending tests were burnished by experienced silver finishers. This process is considered in the trade to be, in addition to a help in finishing, a reliable means of testing the adhesion of the silver. The operation is usually done by clamping the article firmly on a bench and then passing a smooth, dry steel burnishing tool over the entire surface and particularly on the edges. Unless the silver is in closest contact with its base at every point, the deposit will not pass this test without blistering. Every one of the test-pieces, spoons, forks and blank strips, used in the investigation emerged successfully from this test.

Small divergencies in results were noticed between test-pieces made from nickel silver that had been deoxidized and those made from alloy that had not been deoxidized, the former giving better results than the latter for the same grades of alloys, but the number of the latter used were so few that attention is only drawn tentatively to the result, as the authors intend to make further comparative tests in the future.

Results of Microscopical Examinations.—Samples of every type were carefully examined under the microscope at about 40 and 400 diameters, and in special cases at 1000 diameters.

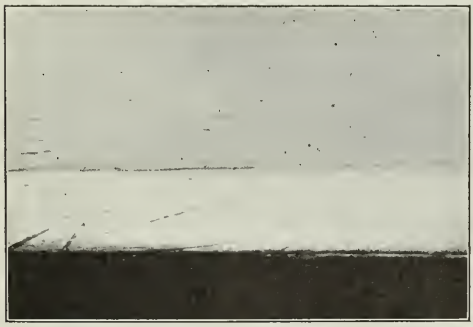


FIG. 2. PHOTOMICROGRAPH OF FIRST-GRADE GERMAN SILVER TEST-PIECE, SILVER PLATED. MAGN. 140 DIAM.

It was found that in every case, when not submitted to strain, the silver deposit appeared closely adherent, and the microscope did not reveal any marked difference between the nature of the junctions of the deposits with the various alloys. Those pieces from which the silver had lifted after being subjected to severe strain showed that the whole of the silver deposit had left the base metal, but in the case of the samples of firsts metal coppered before silverplating part of the copper had remained adhering to the silver and part to the alloy.

The photomicrograph shown in Fig. 1 represents a transverse

section of first-grade German silver coppered before silver-plating. The photograph includes a portion of the place where the mark had been struck, and shows the consequent movement of the two metals. The thin deposit of copper between the nickel silver and the silver is clearly discernible as a narrow dark band. This piece shows the three metals in closest contact throughout.

Fig. 2 shows a transverse section silver deposited on first-grade metal direct. In one place there is a slight indication of parting, evidently caused by the comparatively rough treatment by sawing and filing given during the preparation of the microsections.

Fig. 3 shows in transverse section of the third-grade metal dessert fork with a heavy deposit of silver. In this specimen, even at the highest powers, the two metals seemed to be in closest contact. The line of demarcation seen in the photograph is due to the difference in color between the metal and the alloy.

The scratches are more prominent in the photographs than the authors would have liked, but as the sections are quite sufficiently free for the purposes of their own examinations and records, they did not, when these were originally made, think of wasting any more time on them. When, however, it was decided that they should lay the matter before the members of this Institute, they repaired to the box where all the sections were stored together in order to prepare them more perfectly and a strange thing had happened.

The four most typical specimens which had been photographed had been left on the plasticene that had been used for temporary mounting purposes, and the sulphur that this useful material evidently contains had strongly attacked the samples during the three years or so they were laid away. Not only had the surfaces of all four sections been attacked, but the action extended along the junctions of the silver with the alloys so that the idea of re-preparing the samples until they were practically free from scratches was abandoned. This would really have been an unprofitable work, for the sections show all that is necessary. In the case of such a soft metal it is also a tedious one, for, in contradistinction to a recently published opinion, the authors find such materials as the comparatively hard tempered steels much more easy to polish than soft metals.

Conclusions.

The investigations clearly indicate considerable differences in the adhesion of deposited silver to the various grades of German silver alloys, even when all are treated under the same conditions of practice, and the authors are of opinion that this fact should have full consideration in choosing a basis metal for articles to receive the thickest silver deposits given, which will also be required to bear rough usage.

They are not prepared to state dogmatically that any one particular alloy is best for this purpose, but they consider they have fully proved that ordinary commercial alloys of copper, zinc and nickel containing more than 14 per cent of nickel are of doubtful utility in this respect. On the other hand, alloys of the types of G, F and E used for carrying heavy silver coatings electrodeposited with due care, will endure exceptionally rough usage without giving any cause of complaint on the ground of the silver stripping.

It should be noted that the tendency to strip increases with the thickness of the silver deposit.

The properties considered in deciding upon the grade of German silver to be used as a basis metal for electroplating are strength, color and malleability. As a general rule, passing from G to A in the series of alloys the strength increases, the color approaches more nearly the white of silver and the malleability decreases.

With regard to whiteness, however, where thick coatings of silver are concerned this should not be considered as a matter of such primary importance as the perfect adhesion of the silver under the conditions of wear. Strength is more important than color, and the lower members of the series are deficient in strength; but articles having quite sufficient strength and stiffness can be made of the type of alloy recommended by suitable mechanical and heat treatment.

With regard to the nature of the adhesion, the authors do not at present care to advance any theory to account for the differences described, but as they consider that the quicking process forms a superficial amalgam with the basis metal in the first place, and afterwards on the inner surface of the silver de-

FIG. 3. PHOTOMICROGRAPH OF DESSERT FORK OF THIRD-GRADE GERMAN SILVER WITH THICK DEPOSIT. MAGN. 140 DIAMETERS.

posit, the two amalgams may form a kind of cement between the plating and the basis alloy.

It is possible that with the more suitable alloys this very thin film of amalgam is more efficient than with the alloys of higher nickel content.

Hence, although the investigations at present in train are undertaken with regard to the general properties and structures of the series of nickel silver alloys given in Table I, it is intended to note specially any changes in microstructure among the members of the series, with the view of any possible change in the nature of the amalgam that would be produced. They also, for the same reason, intend, with their new series, to examine, with the highest powers of the microscope, a fresh set of specimens after the most careful preparation. The above idea of the nature of the adhesion is supported by the manner of the tearing of the intermediate film of copper, part of which, as already stated, adhered to the silver and part to the basis metal.

A strongly worded appeal has reached one of us to support a demand for foundation alloys of higher nickel content to be used for the thickest coatings, which, if carried into effect, as in many other cases of undue interference of the buyer with the practice of the best makers, would defeat its own purpose of obtaining the best article for the required use.

It is interesting to note how the metallurgist has to reconsider the properties of his materials and his methods of manufacture in order to be able to make articles that will do him credit in the world's work when new conditions of life arise requiring these articles to bear a different type of usage. It is no use for him to claim that the usage to which his products are subject is unreasonable, if the new conditions of life require them to bear rougher treatment or some other special strain. He has no say in regard to sociological changes, and if he be wise he will just accept the conditions and endeavor to solve the problem. This was the task placed before the authors, and the practical results of their work have stood the severest trials since their earliest investigations were completed.

The Industrial Fixation of Atmospheric Nitrogen.

From a French Chemical Society Paper by E. LAMY.

Translated in abstract by MARK R. LAMB.

Before discussing the fixation of nitrogen it will be well to recall what nitrogen is, its importance and the rôle which it plays in nature.

Nitrogen is a part of all living matter, and plants as well as animals could not do without it while continuing to live and repair their tissues.

Nitrogen appears in nature in compounds, of which the most important is the nitrate of sodium, and in the free state in the atmosphere, of which it constitutes 80 per cent by volume, the balance of 20 per cent being oxygen. The atmosphere which surrounds the earth constitutes, then, an almost unlimited supply of nitrogen placed freely by nature at the disposition of plants and animals. It is true that the latter cannot directly assimilate the nitrogen of the air, but they borrow it from the plants upon which they feed. Now, though all plants require nitrogen, only some of them, such as the leguminous, thanks to certain bacilli, called "bactériocécidées" by Prof. Mattei, can directly fix atmospheric nitrogen. Very interesting experiments made during the last score of years have clearly demonstrated this.

Certain sea weeds have this same ability to fix nitrogen.

But the above classes constitute but a small part of the vegetable kingdom. The great majority of plants, such as wheat, barley, corn, oats and potatoes, upon which man and other animals are nourished, have not this faculty. According to recent experiments a small amount of assimilable nitrogen occurs in the atmosphere in the form of nitric acid and ammonia, but in infinitely small and altogether insufficient quantities for the needs of those plants.

In order therefore that they may grow it is necessary that they draw the required nitrogen from the ground. Now the nitrogen compounds which exist in the soil in its natural state are not sufficient to induce the best growth of plant life. So it is that it has become necessary to add nitrogen to the soil in the form of fertilizer such as manure and other natural products, of which the principal ones are the guano of Peru and the niter of Chile. As farming methods are improved and as farming becomes more intensive it becomes more and more necessary to enrich the land with nitrogen fertilizers to compensate for the elements removed from the soil by vegetable life.

Guano, which is an excellent fertilizer, exists only in small quantities, the deposits being about exhausted.

Fortunately this is not true of the niter deposits discovered in Chile about 1825. The first developments were made near the ports of Iquique and Patillos and afterward on the celebrated and inhospitable desert of Atacama. Now the plants are numerous and occupy an area of 500,000 acres.

The consumption of niter over the entire world is increasing at a rapid rate. The following figures will make this clear. The exportation of nitrates from South America was 800 tons in 1830; 7000 tons in 1835; 20,000 tons in 1850; 70,000 in 1860; 150,000 in 1870; 300,000 in 1880; 800,000 in 1890; 1,300,000 in 1900; 1,500,000 in 1905, and 2,000,000 tons in 1909.

At present the principal consumers of nitrate are as follows:

France	250,000 tons
Great Britain	100,000 "
Germany	500,000 "
Belgium	200,000 "
United States	400,000 "

The price of nitrate varies between 200 and 260 francs ($40 and $50) per metric ton (2204 lb.), and at present the price is 210 francs ($42) at Dunkirk.

The larger part of the nitrate goes to agriculture, but an important part is used in various chemical industries, among which the manufacture of HNO_3 should be given first place, since in France alone this industry absorbs ten to twelve thousand tons annually. Nitric acid is obtained from niter by decomposing the latter with heat by H_2SO_4. The uses for that acid are numerous and we may cite only the manufacture of explosives, of celluloid, artificial silk, dyes, etc.

The available reserves of Chile have been the object of many and widely varying estimates. Nevertheless the deposits are considerable in spite of the statements—perhaps intentionally pessimistic—which have been given out for some time.

According to a report given me by Mr. Paul Lemétayer, professor of applied chemistry at Santiago, a technical commission of the Chilean government has recently made a study of all the nitrate fields now being worked in order to determine the quantity of nitrate of soda which can be recovered by the processes now in use. After an exhaustive study of the fields the commission has arrived at the conclusion that even after prudently reducing the estimate the quantity of nitrate yet to be extracted amounts to 240 millions of tons. Therefore, even after taking into account the increase in the consumption, the supply is sufficient for agriculture and the industries for more than a century.

It should be added that, contrary to what is generally known, the deposits now being worked represent but a small part of the total area of the nitrate region, which covers about 25,000 square kilometers, or 10,000 square miles. This immense zone, which, not including unexplored areas, is over 700 kilometers, or over 420 miles long, will supply all demands for many years.

It seems possible to improve the present methods of working and particularly of treatment and separation of the nitrate from the foreign matter which accompanies it. The government of Chile has established an international competition, with important prizes for any one improving on the more or less primitive processes still in use.

Other deposits of nitrate have been found in California, Colombia and in the Caucasias, but up to the present none is important nor can the deposits be worked as easily as those of Chile.

There are, however, still other sources of nitrogen. For example, certain animal refuse, such as hides, wool, etc., spoiled fish and food, all of which are used as fertilizer after treatment with sulphuric acid.

Coal contains from 1 to 2 per cent of nitrogen, and as 800 to 900 millions of tons of coal are consumed annually in the world a considerable quantity of nitrogen is thus released. However, as at most but 1-20th of that coal is distilled in retorts of producers or coke ovens, and further as only a part of the nitrogen contained is recovered as ammonia, the amount of nitrogen compounds thus actually produced is small.

The recent development of new forms of coke ovens has appreciably increased the world's production of ammonium sulphate, so that this total may be given as 800,000 tons, of which more than 50,000 tons are produced in France. This is therefore an important source of nitrogen for agriculture, which will exist as long as the coal deposits of the globe endure, but it will not make up for the shortage when the natural nitrate deposits are exhausted.

Is, then, humanity, and the white races in particular, destined, after some centuries, to be unable to feed itself on account of the impoverishment of the soil and the failure of the crops? This is a melancholy view of the situation which the illustrious savant, Sir Wm. Crookes, took in 1899 and which he opposed with the statement: "Before we suffer a real dearth the chemist will have intervened and he will have put off the day of famine to a date so distant that we and our children and our great-grandchildren may live without worrying about the future."

These prophetic words of Crookes have been realized. The scientist has turned to the enormous supply of nitrogen contained in our atmosphere, and, thanks to electricity, that benevolent fairy which has again come to the assistance of humanity, they are beginning to exploit this "deposit" and to extract

nitrogen in a form which is useful to the industries and in agriculture.

We will now see how the problem of the fixation of nitrogen has been solved.

The nitrogen compounds obtained are in two forms:

First.—Cyanamide, or "lime nitrogen."

Second.—Nitric acid and the nitrates.

(*A*) *Cyanamide.*

This name is applied to a product composed of carbon, nitrogen and calcium, according to the formula CN_2Ca.

In organic chemistry "amide" is the name for a dehydrated salt of ammonia. Cyanamide CN_2H_2 results in this way from the dehydration of ammonium cyanate, $CNO.NH_4$, according to the formula

$$CNO.NH_4 = CN_2H_2 + H_2O.$$

Calcium cyanamide is a calcium salt of cyanamide CN_2H_2, in that the two atoms of hydrogen are replaced by one of calcium, as is shown in the above formula, CN_2Ca.

Franck, a scientist of Charlottenburg, discovered cyanamide by a lucky chance and without seeking it. With Caro he was studying the preparation of metallic cyanides, such as barium cyanide, when he discovered that the carbides of the alkaline earths absorb nitrogen under the influence of heat—that is, if nitrogen is passed through calcium carbide which is kept at a high temperature, the gas is absorbed; the carbide looses an atom of carbon and is changed to calcium cyanamide,

$$CaC_2 + 2N = CaCN_2 + C$$

In the presence of water (as, for instance, in moist soil) cyanamide breaks up into ammonia and calcium carbonate as follows:

$$CaCN_2 + 3H_2O = CaO.CO_2 + 2NH_3$$

The industrial manufacture of cyanamide was accomplished first in Italy at the Piano d'Orte plant near Pescara, where there are available 25,000 hp in hydroelectric power, then in Switzerland, in Norway[1] and in France (at Notre-Dame de Briançon).

The Société des Produits Azotés has installed an important plant near the carbide factory.

The carbide of calcium used is the ordinary commercial product, 80 per cent pure, yielding 300 liters of acetylene gas per kilogram (4.8 cubic feet per pound). It is crushed, then ground in a closed ball mill in which circulates a current of pure, dry nitrogen to prevent any alteration due to the humidity of the air. The fine product is charged into retorts similar to those used in German gas plants and is heated with coal, or, as is more frequently done, is charged into iron crucibles heated electrically, as at Notre-Dame de Briançon, the charge per crucible being 400 to 500 kg (900 to 1100 lb).

When the temperature is sufficiently high (cherry red), say, 1200° to 1300° C. (about 2200° to 2400° Fahr.), the current of nitrogen is introduced.[2] The absorption of the gas continues regularly and during 30 to 60 hours. The completion of the reaction is indicated by a manometer in the nitrogen pipe line.

As the combination which takes place is exothermic, the quantity of coal or of current required for heating the furnaces is relatively small.

The product obtained is a blackish, porous mass which is immediately crushed and powdered for delivery in 100-kg (200-lb.) sacks.

The percentage of nitrogen varies greatly, from 15 to 20 and even more. It depends on the quality of the carbide employed and also upon the purity of the nitrogen. It is important that the nitrogen should contain no oxygen and should be very dry. For these reasons the Linde and Claude apparatus is usually employed,[3] as this gives a product 99 per cent pure nitrogen.

As this apparatus has been described before let us now only consider the principle involved.

The air passes through towers sprinkled with a solution of caustic soda which fixes the carbonic acid. It is then subjected to a pressure of 4 to 6 kg per square centimeter (57 to 85 lb. per square inch), cooled with water at ordinary temperature and dried by circulating over calcium chloride.

It is then filtered to remove dust together with entrained particles of the reagents used.

The air thus purified is cooled with ammonia to at least 20° to 25° Cent., at which temperature it is put in the counter-current circuit which reduces it 180° to 190° in the coils surrounded by the gas coming from the distilling apparatus, and liquefaction at the valve results.

As in all processes of rectification (fractional distillation), it is necessary to obtain a very low temperature above the distilling apparatus in order to hold back the oxygen and separate the nitrogen, which is the more volatile.

This result is obtained by the use of a refrigerating machine, which consists of nitrogen pumps drawing gas from the upper part of the still, a circulating system parallel to the air circuit and the release of liquid nitrogen on the upper part of the still.

This nitrogen as it descends from one level to the next holds back the less volatile oxygen and thus pure nitrogen is obtained in the upper part of the apparatus with 75 to 80 per cent oxygen at the bottom.

The net cost of cyanamide depends first of all upon the cost of carbide, since 80 lb. of the latter are required for every 100 lb. of cyanamide.

The use of cyanamide as a fertilizer in Europe has formerly disclosed several inconveniences. It could not be used as a soil covering. It had to be scattered at just the right time, either when the ground was being cultivated or when the seed was sown, as the very fine powder was blown about by the slightest breeze. It was also caustic and burned the hands of the farm laborers.

It seems now that a remedy for these disadvantages has been found in slightly moistening the cyanamide without allowing the temperature to rise, so as to prevent any heating which would transform part of the combined nitrogen into ammonia gas. This ammonia would not remain in the highly alkaline and hot mass and it would be released with what would represent a considerable loss.

After this moistening, which eliminates all traces of undecomposed carbide, the product is oiled with cheap hydrocarbons—petroleum in Germany, and coal oil in France—which gives a commercial fertilizer which is not dusty nor caustic.

A patent has recently been applied for mixing oxide of iron with cyanamide powder, which gives a granular product of good appearance and which it is easy to use.

(B) Nitric Acid and Nitrates from Air.[4]

We have now reached the second method, which is also the more interesting, that is, the production of nitric acid and nitrates from the nitrogen of the air.

Many processes have been designed during the last few years. We will not discuss all of these but will deal only with the three processes which are really practical and which are now in actual operation, and which consequently will interest engineers. These are the processes of Birkeland and Eyde, of the Badische Anilin und Soda Fabrik and of Pauling.

1. *The Birkeland and Eyde Process.*

In the apparatus[5] used by Birkeland and Eyde the principal and most important item is the furnace (Fig. 4 on page 74).

---

[1] A large Norwegian calcium carbide and cyanamide works was described in some detail in our volume VII, pages 212, 309, 360 (May, July and August, 1900).—Editor

[2] The temperature at which cyanamide begins to form is not more than 800° to 1000° C. (about 1500° to 1800° Fahr.). Since the reaction is endothermic, it evolves so much heat that no large supply of electrical energy from the outside is necessary.—Editor.

[3] In some cyanamide plants, instead of the liquid air process, a simple chemical method of burning out the oxygen from the air by means of copper is employed. The copper is mixed with asbestos to give a large surface and the oxide is reduced either with methane or with producer gas. The process is exceedingly simple on paper, but has given a good deal of trouble in practice on account of the excessive heat produced.—Editor.

[4] This part of Lamy's paper has been considerably abstracted to avoid repetition of what has been discussed at length formerly in this journal. Compare also the article on page 73 in this issue.—Editor.

[5] See also page 73 of this issue; further our vol. II, page 399; vol. IV, pages 126, 295 and 360; vol. VII, pages 304 and 305; vol. VIII, page 451.—Editor.

The arc is given a very great surface by means of the deviation produced by an electromagnet. The arc is thus caused to take the form of a flat disk with a diameter of 6 ft. in commercial furnaces. The general form of the furnace resembles a thick lens. It consists of two thick cast-iron shells which surround and support the refractory material. These are cored for air and gas circulation, and between them is a space 3 to 4 in. wide and 6 ft. long, which is the oxidizing chamber in which the electric discharge is maintained.

The electrodes consist simply of copper tubes bent in U-shape and cooled by a circulation of water so that their temperatures are never high. Fig. 4 on page 74 shows a vertical section of this furnace. The oxidizing chamber is represented by the restricted space between *a* and *a*. The electrodes, only indicated in the figure by the little circle in the center, are perpendicular to the plane of the drawing. The poles of the electromagnet are shown at the right and left, carrying the magnet coils. The current of air under pressure from a blower circulates in the furnace in the direction shown by the arrows. It enters through the two ducts at the right and left, shown at the bottom of the diagram, passing through two distributing chambers and through a large number of small tubes to the oxidizing chamber in the center. It is conducted from this through the annular canal *a a*, which surrounds the oxidizing chamber, finally escaping at about 1000° through the central exit duct to the apparatus which we will take up later.

It seems that the Birkeland furnace is remarkably durable, as it can run a year without excessive maintenance and repair charges. The refractories need replacing every five or six months and the electrodes every three or four weeks.

A number of furnaces of this type have been built at Notodden which vary in the amount of power required from 250 to 4000 hp.

The necessary electric current is supplied by the Svaelgos plant in the form of three-phase, 50-cycle, 10,000-volt currents.

2. Badische Company Process.

The engineers of this company, Dr. Schönherr in particular, in 1905 invented a different furnace system which is now being tested in the Norwegian plants, where it seems to be giving good results.[6]

The furnace of the Badische Company seems simpler than that of the Norwegian company. Its construction is cheaper, while all the costly and delicate mechanism necessary for creating the magnetic field is avoided, but it is more difficult to operate and requires more attention. The quantity of NO produced is practically the same, but the percentage of NO in the gas mixture is higher, that is, the effluent air contains 2 per cent of NO corresponding to 0.050 gram HNO_3 per liter (0.05 oz. per cubic foot), while the product from the Norwegian furnace contains from 0.03 to 0.04 gram per liter (0.03 to 0.04 oz. per cubic foot).

Several Badische Company furnaces have been built, but at the present writing they cannot use more than 700 to 800 kw, as already with this power the arc has reached a length of 7 m. (22 ft.). The two largest Birkeland and Eyde furnaces have a capacity of 4000 hp (2940 kw) each.

The average productions of the furnaces, which, as we have said, are practically equal, vary from 570 to 600 kg of HNO_3 (or from 12,500 lb. to 13 500 lb.) per kw-year. It does not seem possible to easily improve upon the latter figure. For a 750-kw furnace this represents 440 to 500 tons of HNO_3 per year, which is equivalent to 800 tons of commercial acid of 36° Baumé.

The Norwegian furnaces, which have been in use for several years at Notodden, have proved themselves eminently practicable. The Badische furnaces, which have been under test for some months, have behaved well up to the present, and it is difficult to choose between the two types, so much so that the Norwegian company intends to use both in the new works which it proposes to build.

But let us return to the gas which flows from the furnace of either system. This gas, consisting of a mixture of NO with a large excess of air, is, as we have said, at a temperature of 700° to 800° C. and even of 1000° to 1100° C. with the new 4000-hp furnaces. This temperature is much too high to permit of the gas being immediately conducted to the absorption towers. It is, therefore, cooled to 40° C. by being conducted through large boilers (the steam from which is used in evaporating pans which we will describe later), then through air-cooled aluminium pipes, the air thus heated being conducted to the furnace. Aluminium pipes are used because this metal is not attacked. The cooled gas is conducted to a sheet-iron tower lined with refractory material where the oxidation is continued and completed at the expense of the oxygen of the air. Then it is conducted to the high absorption towers, which are of two kinds. One is of Drammensfjord granite, not affected by acid, and with joints of asbestos and silicate of soda; the others are simply of wood.

The three granite towers are 34 m. (100 ft.) in diameter and 20 m. (65 ft.) high. They are filled with pieces of quartz which are continuously sprinkled with acid solution. The gas as it traverses successively the three towers is brought into contact, following a definite course, with more and more dilute acid.

In this way the strongest acid, which is taken from the bottom of the first tower, contains 500 grams of HNO_3 per liter, while pure water enters the top of the third tower. If the manufacture of calcium nitrate is the only object in view, it is useless to push the concentration too far, and in practice the acid is drawn off containing only 300 to 400 grams of nitric acid per liter.

The handling of this liquid is accomplished automatically by the use of montejus made of pottery which is not affected by the acid, and operated with compressed air.

At the gas outlet of the last tower about one-quarter of the NO is still undissolved. To catch this it is necessary to use an absorbent which is more energetic than water, such as a solution of soda or lime. This absorption is carried on in two towers filled with pebbles or pieces of granite. The absorption is so nearly complete that the gas discharged to the atmosphere contains but 4 per cent of the combined nitrogen, that is, 96 per cent of the NO has been recovered in the towers in the form of nitrogen compounds.

The liquid flowing from the wooden towers is a mixture of solutions of nitrite and nitrate of calcium if milk of lime has been used. This mixture is treated with nitric acid produced in the plant itself. The nitrous acid which is freed is conducted to the absorption towers.

If instead of milk of lime a solution of carbonate of soda is used as a spray in the wood towers, as is the general practice, the resulting solution is concentrated and the nitrate of soda is separated by crystallization and is a product in demand for the manufacture of dyes.

The nitric acid coming from the granite absorption tower is too weak to be put on the market. It can be concentrated to a commercial standard strength of 36° to 40° Baumé, and at present deliveries of this strength are being made in Norway. Eyde claims to have secured a 96 per cent concentration of nitric acid, but I have not yet been able to find that the Norwegian works have produced and sold acid so concentrated. They generally prefer to use the tower acid for the manufacture of calcium nitrate.

To do this, the acid is conducted to granite vats filled with coarsely broken limestone, which is rapidly attacked. When the solution is neutral—determined by adding a small amount of milk of lime—it is concentrated by evaporation in a Kestner apparatus, using the steam from the above-mentioned boilers, which are heated by the gas from the furnace. The material,

[6] This furnace is illustrated in Fig. 6 on page 74. For further details see also our vol. VII, page 245.—EDITOR.

kept in fused state to a temperature of 145° C. may be poured into thin-sheet iron cylinders where it solidifies upon cooling. It may be then sold in this way to chemical manufacturers, but it is generally solidified in cast-iron molds, crushed and pulverized and packed in 220-lb. barrels for delivery to the farmer.

The adjoining diagram is a flow-sheet of the above-described operations. 1 is the blower, 2 the electric furnace, 3 the boiler, 4 the cooler, 5 the oxidation tower, 6 the three absorption towers of granite, 7 and 8 the two absorption towers of wood, 9 the final nitric acid, 10 the nitrite solution. *A* is the apparatus for the production of saltpeter, *B* the apparatus for the production of nitrite, 11 solution tank, 12 a neutralization tank, 13 and 18 are Kestner evaporators, 14 solidifying tank, 15 crushing, 16 montejus, 17 receiver, 19 crystallization, 20 filter, 21 mother lye, 22 centrifuge, 23 montejus and 24 receiver.

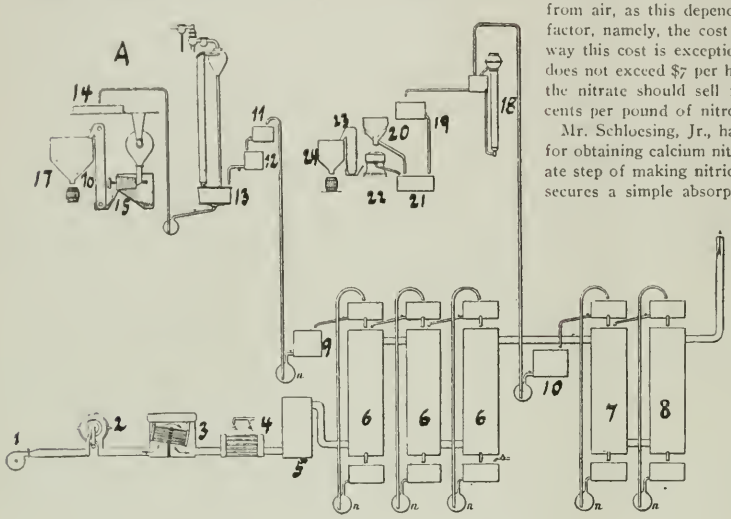

FIG. 1.—FLOW SHEET OF BIRKELAND-EYDE PLANT.

The calcium nitrate thus obtained contains an average of 13 per cent of N and is an excellent fertilizer. The tests made both in France and abroad are conclusive in this respect.

Mr. Malpeaux, director of the Agricultural College of Berthonval, has begun a comparative study of sodium nitrate and the Norwegian calcium nitrate. During several years he has experimented with various plants, such as wheat, barley, sugar beet, potato, poppy and onion.

"We may conclude," Mr. Malpeaux remarked, "from our experiments that the calcium nitrate such as is furnished by the factory at Notodden at least equals sodium nitrate. While the former furnishes the plant with the calcium nitrate already formed, providing nitrogen and calcium at the same time, the sodium nitrate is changed in the soil to calcium nitrate and the remaining sodium salt is of no use to the plant. It is then in the form of calcium nitrate that the crop utilizes the nitrogen, and it is, therefore, not astonishing that under certain conditions the action of the Norwegian nitrate should be superior to that of sodium nitrate."

The opinions of scientists and farmers in other countries concerning the qualities of calcium nitrate seem to be the same as those of their French colleagues.

Using equal weights of calcium and sodium nitrates—from 100 to 300 lb. per acre, according to the crop—identical results were obtained, even though sodium nitrate contains 2 to 3 per cent more nitrogen, or 15 to 16 instead of 13 per cent nitrogen. In certain countries, especially in Germany, the prices of the two are the same. This is not true in France, where the nitrogen content is taken into consideration. If, for example, nitrate of soda is worth $1.90 per 100 lb. at Dunkerque, calcium nitrate sells for $1.70 per 100 lb. at Rouen.

The one slight disadvantage of the calcium nitrate is that it is hydroscopic, which makes it difficult to spread in the wet season, especially by the use of machinery. It is always best not to open the barrels until the moment when the material is to be used. Means are now being sought to diminish the hydroscopic nature of the product.

It is very difficult to state the net cost of producing nitrate from air, as this depends principally upon a very variable factor, namely, the cost of an electrical hp-year. In Norway this cost is exceptionally low, it being claimed that it does not exceed $7 per hp-year. Under such circumstances the nitrate should sell for $1.15 per 100 lb., this being 9 cents per pound of nitrogen.

Mr. Schloesing, Jr., has invented and patented a process for obtaining calcium nitrate directly without the intermediate step of making nitric acid as we have described it. He secures a simple absorption of the nitrogen oxide gas by lime. After having first dried the air entering the furnace, he conducts the gas leaving the furnace (cooled to 300° or 400°) to large sheet-iron chambers containing lime prepared in the following manner: Ordinary limestone is crushed and molded into briquettes and heated to the temperature of dehydration. These briquettes have the property of very easily absorbing the nitrogen oxide vapors at 300° to 400° C. He obtains a complete absorption of the NO and with an apparatus much smaller than is required by the other process. Moreover, the nitrate obtained contains 14.5 to 15 per cent of nitrogen. The process requires comparatively very simple apparatus and therefore entails a considerable economy in a given industrial application.

A small-scale test of the process has been made at Notodden which confirms all that Schloesing has claimed. There is therefore, reason to believe that a large-scale application will soon be attempted.

3. *Pauling Process.*

We will now describe our third practical process for making nitrates from air, that of Pauling.[7]

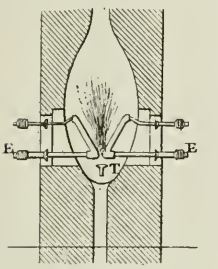
After numerous and long laboratory tests Pauling make his first installation in 1904 in the plant of the Saltpetersaure company, at Patsche, near Innsbruck, in Austria. Since then he has made a series of improvements on his process so that he now has made it a truly practical industrial process. In 1908 a French company, La Nitrogene, acquired the French rights to the Pauling process and is now exploiting it in a recently built plant at Roche-de-Rame, near Briançon.

We have visited this plant and we will now proceed to describe it from our own observations and from data kindly supplied us by the manager, Mr. Mollard, and the engineer, Mr. Gros.

Let us first go into the fine, large furnace room. The furnaces appear to be nearly square (3 ft. 3 in. by 3 ft. 8 in.), they are 10 ft. high and built in groups of three. Built as they are of simple masonry of refractory brick and stayed with iron, they show to a first glance two important qualities, simplicity and strength. The essential part is a vertical slot of refractory brick in which are placed the hollow cast-steel electrodes ar-

[7] See Fig. 3, page 73, of this issue; also our Vol. VII, page 430, where the Innsbruck plant is described.

ranged as shown in Fig. 2. They are reversible and interchangeable. Just below the space between these two electrodes and in the same vertical plane with them is the opening of a flattened tuyere *T* through which the hot compressed air reaches the furnace, the force of which serves to blow the arc. There is here a difficulty to overcome. It is necessary that the space between the two electrodes should be sufficient to pass the necessary quantity of air, but at the same time it should be constant and not extinguish the arc as it lengthens. Pauling has ingeniously supplied the main electrodes with auxiliary, movable copper knife-blade electrodes, the extremities of which can be brought near enough together to lure and start the arc as soon as it goes out, thus requiring a relatively low voltage.



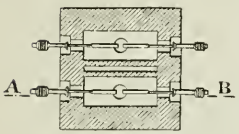


FIG. 2. PAULING FURNACE.

The positions of the main electrodes are adjustable by means of screws, and of the knife-blades by a rack and pinion. These maneuvers are very easily made from without the furnace, the electrodes and their adjustments being protected by movable screens.

Under the influence of the jet of air from the tuyere the arc, rising between the copper blades, spreads to the tops of the horns of the electrodes and produces a flame 3 ft. to 4.5 ft. high. The combination of O and N in form of NO and nitrous vapors is made at the contact of the flame and the incoming air. In order to obtain a rapid cooling of the mixed gases, a suitable current of air is admitted at the bottom of the furnace. The furnace is provided with permanent peep-holes for examining the knife-blades, electrodes and tuyeres, to assist in maintaining the furnace in certain and constant operation.

The copper blades last for 20 hours and can be replaced in two minutes. The electrodes are replaced with equal facility. They are good for 500 to 600 hours, thanks to the cooling effect of the circulation of cold water and also to the interesting peculiarity that the hottest part of the flame is the upper part, that is, the point at greatest distance from the electrodes.

An opening in the gas discharge channel permits the introduction of a pyrometer to measure the temperatures.

Each furnace includes two arcs in series using a three-phase 50-cycle 4000-volt current. The electrical equipment consists of two small coils, a small transformer and a starting box. All this is placed on the wall of the room in front of the furnace. The operation of the apparatus is simple and without danger. I have tried it myself. As soon as the switch is closed the furnace begins normal operation and one man can care for two batteries of three furnaces. Nine furnaces are now in operation. Each absorbs 500 hp, but it is expected to raise this figure to 600 and then to 700. The production will be proportionately improved, as was demonstrated in the Pratsche plant with furnaces consuming 1000 hp and even 1500 hp.

But, let us suppose that the furnaces are in operation. We have said that the air is brought to them through large conduits underneath, and that the air blows through the tuyeres, coming in contact with the long electric flame where the combination already explained takes place. The mixture of gases containing 1.15 per cent to 1.20 per cent of NO goes out at a temperature of 700° to 750° and immediately enters a cooling chamber, where it gives up part of its heat to the air which is on its way to the furnace. The gas is then conducted through two masonry flues alternately. While one is cooling the gas the other is connected to the atmosphere through a chimney, which cools it ready for use as soon as the other becomes too hot, which is usually after a period of six hours.

After being drawn through an exhauster which creates a suction as far as the furnace, the gas at a temperature of 35° C. enters a large oxidizing tower, made of reinforced concrete 35 ft. in diameter by 70 ft. high. It is in this tower, on account of its large volume, that a complete mixture is obtained and a prolonged contact provided and a complete oxidation of the lower nitrous vapors secured.

An earthenware conduit then carries the acid gases to the absorption towers, five in number. These towers are built of refractory brick and contain a material unaffected by the acid (similar to what is employed in the glover towers of sulphuric acid plants) over which flows pure water or water already acidulated in order to obtain a regular absorption.

A series of automatic earthenware montejus are used in handling these liquids.

The strong acid comes from the first tower. The acid reaches 5° Baumé in the fifth tower, 8° in the fourth, 12° in the third, 15° in the second and finally 25° to 30° in the first, which means 35 per cent to 40 per cent of nitric acid.

This strong acid is put in porcelain capsules, which are placed in a kind of Benker furnace, where it is concentrated by the hot gases which come directly from the furnace. The entrained water vapor is recovered from the cold gas in one of the absorption towers. The concentrated acid goes through a cooling coil of earthenware to large reservoirs, from which it is drawn for shipment.

This acid contains from 60 per cent to 62 per cent nitric acid and, therefore, measures from 38° to 40° Baumé, which is a good degree of commercial concentration.

The Innsbruck works, with special apparatus, is able, it seems, to push the concentration to 97 per cent nitric acid, which corresponds to more than 48° Baumé. It is also proposed to produce an acid of similar concentration at Roche-de-Rame.

Upon leaving the absorption towers the remaining gases are conducted through wooden towers containing soda solution and are then allowed to escape. A certain amount of nitrite of sodium is thus obtained, which, after concentration, crystallization and treatment in a centrifugal drier, is marketed in a crystal form, 97 per cent to 98 per cent pure.

Ninety-six per cent of the NO is recovered during normal operation. The yield amounts to from 65 grams to 70 grams (or 2.3 oz. to 2.5 oz.) of nitric acid per kw-hour consumed, or 1100 lb. to 1300 lb. per kw-year, or, again, about 2200 lb. of 36° commercial nitric acid, as in the Norwegian furnaces.

As regards net cost of production we must repeat that it depends largely upon the cost of power. The rather vague data on this subject which we possess does not permit our giving accurate information.

Taken as a whole, the Pauling furnace appears simple, compact, to require inexpensive repairs and the whole process should be practical; in fact, it appears that the Pauling plant particularly has reached a point where it runs regularly and with commercial success.

The Roche-de-Rame plant gives the visitor a curious impression, as do other similar plants. There are few men, no noise outside of the building of furnaces and, above all, no visible raw material, these being restricted to water and air, the entrances of which are not noticed.

But there is one very important element which enters quietly on copper and aluminium wires. That it plays an important part in the net cost can easily be seen in the above-quoted figures of production per kw-hour. It requires a kw-year to produce a single ton of calcium nitrate of 13 per cent nitrogen. Power must, therefore, be obtained in large quantities at a low price. Thus recourse must be had to "white coal" (the French name for waterfalls as producers of electrical energy).

At Roche-de-Rame water-power is obtained from the

Biaisse River, an affluent of the Durance. Four sets of 2000 hp have been erected and considerably more power is being sought.

But, as regards natural power, Norway is a privileged country. It is on this account that it has been considered feasible to create the new industry there, and that the powerful Norwegian Nitrogen Company, with a capital of $8,000,000, has built its plants in that country.

But Norway is not the only European country in which important available waterfalls can be found. In France, particularly, there are still good hydraulic powers available in the Alps and in the Pyrénées, and, even if the cost per horse-power of installation be appreciably higher than in Norway, it should be possible to reach a reasonably low net cost of production if the right to use processes can be obtained at a reasonable figure. It is, therefore, probable that other companies will follow the example of the Nitrogen Company and construct more plants in France to use one of the described fixation processes.

The fixation of nitrogen, due to the fruitful collaboration of scientist and engineer, constitutes one of the great discoveries of modern times—one of the most useful, undoubtedly, to agriculture.

That industry has no reason to fear the lack, even at a remote period, of the nitrogen fertilizers which it must have to support humanity. If even neither the niter deposits nor any of the other sources of nitrogen become exhausted, the farmer will find in calcium nitrate an inexhaustible supply of fertilizing material, because it will be possible to produce it so long as our earth is surrounded by its atmosphere and supply limestone—so long as water evaporates from the sea and, precipitating as snow and rain, forms torrents which descend from the mountains.

Thus will be realized a wish expressed by Renmaux, who said: "We should make the conquest of Nature by means of Nature herself."

Paris, France, and Lima, Peru.

Synopsis of Metallurgical and Chemical Literature

Iron and Steel.

Crystalline Structure of Iron at High Temperatures.—Walter Rosenhain describes in the *Physikalische Zeitschrift* of December 1, 1910, tests with iron and iron alloys to determine the nature of the change going on in iron and steel at high temperatures. As it was necessary to keep the original polished surface of test piece free from all oxides, even at temperatures above 1000° C., the iron was heated by an electric arc in a very high vacuum and tests were made in a specially constructed apparatus with a spring to test the effect of tension. Soft steels, electrolytic irons of great purity and almost chemically pure iron were tested. The conclusions may be summed up as follows: Iron up to 1100° C. acts like a crystalline aggregate and a plastic change of form takes place along the plane of cleavage of crystals of which it is composed. Between ordinary temperatures and 1000° C. iron exists in three modifications which have different mechanical properties. The temperatures within which these modifications take place can be identified with the three forms, alpha, beta, gamma, of iron according to the Osmond and Roberts-Austen theory of allotropic forms. The beta-iron forms at higher temperatures but is stronger and harder than the alpha-iron. It changes from the alpha-state into beta-state with an accompanying change in volume. Almost pure iron at high temperatures has the characteristic structure and a few characteristics of gamma-iron, as is also the case in several steel alloys. The existence of a hard beta-iron modification is also proven at high temperatures; failure of iron quenching is due to difficulty in preventing change from beta-state to alpha-state by this method. Evidence points to the fact that beta-iron if it could be kept unchanged at ordinary temperature would be very hard.

Direct Reduction of Iron Ores in the Electric Furnace.—Mr. G. Arnou in *La Revue de Metallurgie* December, 1910, discusses the new electric furnace of the La Neo-Metallurgic Company for the direct reduction of iron ores. The Chaplet-Neo-Metallurgic furnace is used, the design of which is shown in Fig. 1. It is an arc furnace; the current enters through one or more vertical electrodes and leaves through one or more side channels *B*. The latter are connected with the main bath *A* by horizontal channels *C* below the level of the bath. The slag is charged first, then the ore to be reduced mixed with carbon in proper proportions. Then the reduction begins under the action of the arc and the reduced metal filters through the slag and collects on the bottom. The furnace works similar to a small blast furnace where there is also a separate reducing and fusion zone. More than 15 tons of metal have so far been produced. The slag contains in normal operation less than 8 per cent iron oxide. The charge was a mixture of hematite ore and dried, powdered charcoal. Dried hematite briquets and wood charcoal and later mixtures of carbon and hematite in form of powdered dust were also tried.

With ore and carbon the furnace produced 77 lb. iron per hour.

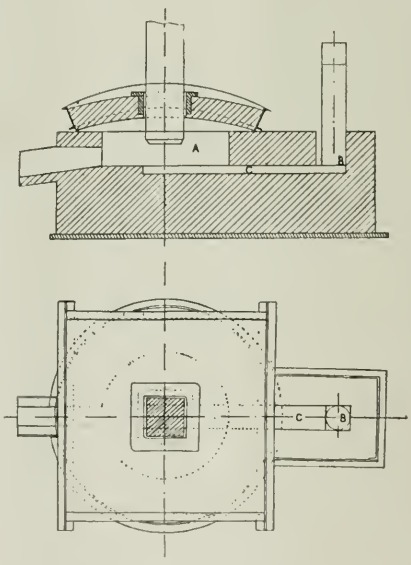

FIG. 1.—ELECTRIC FURNACE FOR STEEL FROM ORE

With briquets the furnace produced 70 lb. iron per hour.

With powder (dust) the furnace produced 68 lb. iron per hour.

The consumption of carbon was different in the three cases, being 660 lb. in the first and 726 lb. and 792 lb. per ton in the second and third cases. These differences are due to the hygroscopic nature of wood charcoal, the evaporation of the water consuming considerable heat. The differences are less if coke or anthracite is used instead of charcoal. In all cases it is possible to treat pulverized ores in this electric furnace, and even a mixture of hematite and retort coke in the powdered state without difficulty. Comparative tests were made, smelting hematite, magnetite, and siderite with coke, charcoal, and

anthracite. It does not make much difference which of the three forms of carbon is used. With charcoal the voltage tends to remain higher than with coke or anthracite, but this is not a serious defect. As regards thermal efficiency anthracite gives the best result. Reductions of hematite with charcoal produced 68 lb. per hour, while anthracite gave 84 lb. an hour with the same electric energy consumption. In the first case 792 lb. carbon per ton of iron, in the second case 596 lb. were used. Magnetite gives better returns than hematite with charcoal. Reduction of magnetite briquets produced 90 lb. per hour, whereas hematite gave only 70 lb. With anthracite both ores gave about the same result. The siderite was easily reduced, but with a large consumption of energy, yielding only 64 lb. per hour for the same energy consumption. Products obtained when analyzed gave the following results:

Carbon	Manganese	Silicon	Sulphur	Phosphorus
0.08%	0.10%	0.02%	0.02%	traces
0.09%	0.09%	0.04%	0.02%	"
0.11%	0.46%	0.06%	0.02%	"

In the last case a large addition of ferromanganese had been made for comparison. These results were obtained by direct reduction from the ores. The iron is perfectly malleable and can be hammered cold into thin sheets. After tempering it bends at 180° even with 0.20-0.25 per cent carbon, which fact is due to its small percentage of manganese. It has great tenacity. As to the cost, it is stated that most of these tests were made with a 120-kw furnace. In the reduction of hematite with charcoal for the production of soft iron the consumption was 3,430 kw-hours with a 120-kw furnace and 2,600 kw-hours with a 200-kw furnace. Studies in regard to the influence of the forms of ores and carbon compounds used as charge on the amount of energy used for the production of 1 ton of soft steel gave the following results:

Magnetite and charcoal	3,150 kw-hours
Magnetite and anthracite	3,050 kw-hours
Hematite and charcoal	3,430 kw-hours
Hematite and anthracite	3,100 kw-hours
Siderite and anthracite	4,000 kw-hours

These tests were made in a 120-kw furnace. For a 200-kw furnace the efficiency is as high as 80 per cent.

As to the cost of maintenance it is pointed out that the arc in this furnace is entirely enclosed by the charge, which absorbs all the heat of radiation, so that the heat losses are small. The wear and tear are small. During the entire time of the tests the furnace used was not repaired and was as good at the end of operations as at the beginning. The amount of carbon in the charge varies with the different mixtures. Reduction of powdered hematite required 792 lb. charcoal and 594 lb. anthracite per ton of iron. Magnetite under same conditions required only 682 lb. charcoal and 572 lb. anthracite. As a rule 55-77 lb. of electrodes are consumed for the production of a ton of soft steel.

Gold and Silver.

Milling at Cobalt.—An interesting feature of ore dressing at Cobalt, Canada, is that the methods in use had to be devised especially for the ores of the district. No precedent could be referred to by the metallurgist and it is greatly to his credit that he has succeeded so well. In the *Mining Journal* (London) for Dec. 17 and 24, 1910, Dr. JOSEPH T. MANDY has given the results of his observations on the work at Cobalt. At present thirteen mills are in operation by electric power, and three more are in course of erection. Wet methods of dressing are adopted, and in some cases hydrometallurgy is practiced to the extent of the final recovery of the metals at the mill.

No two mills are exactly alike, but are the same in general principle. For illustration, the equipment and practice of the Coniagas mill may be taken as typical. The ore is crushed in Blake and gyratory crushers to 1½ in., then rolled to ¾ in. and screened in trommels. The coarse is concentrated in Harz jigs and the fine on Wilfley tables. The residue from these is crushed in 30 stamps, following which the pulp is thickened and treated on Deister and Wilfley tables, followed by a canvas slime plant.

Considerable difficulty was experienced in the early work in saving values from the tailings, owing to the escape of small scales of metallic silver and smaltite which seemed to have a great tendency to float away. By paying more attention to the slime recovery this loss has been largely averted. The average extraction in the district is probably 82 per cent. During 1909 the ratio of concentration was 39 to 1. The cost of milling was higher in 1909 than in 1910 owing to the use of cheaper electric power in the latter year. The cost of the work at the McKinley-Darragh mill was $1.98 in 1909, and is reported to be about $1.30 in 1910. Power formerly cost in the neighborhood of $150 per hp-year, and is now obtainable at about $50.

At three plants—the O'Brien, Buffalo and Nova Scotia—cyanide plants are operated in connection with the concentration. Dr. Mandy considers the success of this process as yet problematical. The Nova Scotia plant uses pan amalgamation and cyanidation, but no figures are available on the success of this system.

The concentrating plants all treat what is known as the low grade ore, containing 10 to 40 oz. silver.

The high grade ore, varying from 100 to 3000 oz. silver, is treated in smelters. The smelting ore is further divided into low and high grade; the first carrying from 100 to 600 oz. silver and the last from 800 to 3000 oz. The purchasers pay a sliding scale according to the silver content, and have various schedules for the arsenic content. United States smelters treated 2/3 of the tonnage in 1910, and Canadian plants treated about 32 per cent, the balance going to England and Germany.

The ores are silicious and make a good fluxing ore in silver lead smelting. They also may be used for converter lining, but for this purpose there are several objections, viz., the arsenic fails to volatilize completely, and practically not at all after the first 10 min. of blowing, causing about 1.5 per cent of arsenic to appear in the copper; the slag is inclined to be thick; the charge effervesces owing to carbonates in the ore, causing high copper slags, sometimes as high as 15 per cent; alumina frequently has to be added to the ore for binding; and finally, the lime and iron in the ore tend to rob the lining of active silica, leaving less to do the work of slag production.

Milling Native Silver Ore in Mexico.—A combination of amalgamation and cyanidation for silver ore is described by WALTER M. BRODIE in the *Mexican Mining Journal* for January, 1911. The ores of the Batopilas silver mines are peculiar in that the clean base minerals, galena, blende and pyrite, seldom carry more than 4 oz. silver per ton. The values occur mostly as native silver, argentite and sometimes arsenical silver.

The ore is sorted into two classes, the high grade native silver ore which is treated without concentration, and the low grade milling ore which is concentrated.

The high grade ore is stamped through a fine screen. Some coarse native silver accumulates in the mortar and is removed and washed by hand prior to smelting and refining. The screened material is amalgamated in pans by the following process: The charge for a 4-ft. pan is 1000 lb. ore, 15 to 17 lb. mercury, 4.5 lb. cyanide of sodium, about 4 oz. lead acetate, 3.5 lb. lime, and 1 to 1 of stock solution. The solution in the pan then runs from 40 to 48 lb. cyanide per ton, and never below 33 lb. The ore is first ground for six hours without mercury, when it is added and grinding continued for 10 hours. The charge is then run into a settler where it is leached and agitated, mechanically and by air, for 12 hours. The settler is then washed four hours, and the amalgam and residues removed and washed by hand. The former is prop-

erly retorted, and the latter is sent to percolating tanks, referred to later.

The slime washings from the settler are thickened in a Dorr machine, the clear overflow of which goes to strong solution sumps, and the thickened underflow to Pachuca tanks. One of the latter is filling while the other is being agitated and drawn off. Blaisdell filters are used, four charges being put through in 8 hours. The tailings from the filter run about 9 oz. silver per ton.

The low grade ore is concentrated 50 into 1. The concentrate consists of pyrite, galena and blende, with native silver and argentite. It is reconcentrated into two classes, high and low grade. The high grade is amalgamated in a pan, adding mercury pound for pound of silver contained, and a slight excess. Grinding proceeds for 14 hours before amalgamation is started, this being continued for 2 to 5 days. Cyanide, lime and lead acetate also form a part of the charge, and the pan is decanted twice daily into the rich solution sump, the solution being made up again with stock solution holding 10 lb. KCN per ton. After 6 days the pan is discharged into a settler, where it is agitated mechanically and by air for six days, the solution being decanted once a day. The tailings from the settler go to the Dorr thickener, and thence to the Pachuca tanks.

The low grade concentrate, which forms the bulk of the product treated, is leached in the percolating tanks referred to above. The charge consists of from 35 to 60 tons of ore; the chemicals added being lead acetate, lime and cyanide. The latter is added in sufficient quantity to make 50 lb. KCN per ton. The solution is left on 24 hours, then drawn off and the tank allowed to aerate for 48 hours. Stock solution of 10 lb. KCN per ton is then run on and allowed to stand for 12 hours, after which it is withdrawn and the tank allowed to stand dry for 24 hours. This process is continued with 12 hour periods of percolation and aeration for two months, when 95 to 96 per cent of the value has been leached from the concentrate. The precipitated silver assays about 800 fine, and the refined product about 990 fine.

Classification of Tailing Pulp Prior to Cyaniding.—For the clean separation of sand and slime a number of schemes have been devised with greater or less degree of success in operation. In the October, 1910, issue of the *Journal* of the Chem. Met. & Min. Soc. of S. Africa, E. H. Johnson gives some results obtained with a plant of the type invented by W. A. Caldecott some time previous, and described by him in the same publication, August, 1909. The idea consists in classifying the pulp in primary diaphragm cone classifiers, washing the underflow in secondary diaphragm cones, finally delivering the separated sand to a horizontal revolving filter table where excess moisture is removed by vacuum, and the dried sand plowed off and transferred to cyanide tanks.

Mr. Johnson gives results obtained at the East Rand plant, where four 20-ft. sand filter tables are in use, with their complement of four 9-ft. primary cones and two 5 ft. washing cones. This plant has for some months handled the sand from approximately 4000 tons of tailing per day. A little over 50 per cent of the pulp is separated as a slime with less than 2 per cent remaining on a 200-mesh screen. The sand contains about 1 per cent slime as determined by elutriation, while 88 per cent is 200 mesh. Not only is the size separation efficient, but the bulk of the pyrite is retained in the sand.

The cubic space occupied by the sand and slime produced by this process is greater for the sand and less for the slime than under former conditions. This indicates that the interstitial spaces of the sand are more nearly true voids than under the old system which left more or less slime in the sand. Tests on 20,000 tons of sand indicate 23.5 cu. ft. to the ton. The extraction is accordingly more rapid, as shown graphically in the original paper. The essential difference between this system of diaphragm cone classification and all previous efforts in the same direction, is the maintenance of a large underflow of minimum moisture, the slime elimination being proportionate to the reduction of moisture in the underflow.

Gold from Clay Deposits.—*Metallurgie* of Dec. 8, 1910, brings a note on a new method of winning gold from clay deposits, due to J. J. W. H. van der Toorn (German patent 225,810). The processes now employed treat clay with water whereby a good deal of the gold is lost, as the separation of gold from clay is very difficult on account of the great cohesion of the clay. The new process tries to remove this cohesion. The gold-containing clay is spread over a large area, dried and kneaded. Then it is heated in a furnace similar to a brick kiln, till it assumes the hardness of stone. The rocklike masses are then broken in a stamp mill and the gold separated in the usual manner.

Copper.

Early Pyritic Smelting at Leadville.—An interesting article on the operation of the old Bi-Metallic Smelter at Leadville, is contributed to the December, 1910, *Bulletin* of the Amer. Inst. of Min. Eng., by Charles H. Doolittle and Royal P. Jarvis, respectively former superintendent and chief chemist at the plant.

Pyritic smelting of raw silver and copper bearing ores was commenced at Leadville by the Bi-Metallic company about 1892 in a remodeled lead smelter, known as the La Plata. After the success of the process was established a new plant was erected in Sept., 1893, and operated until the spring of 1900. Its success was based on the excellent facilities for obtaining suitable ores; heavy sulphides for the production of a preliminary low grade matte, and rich silicious ores for the second smelting and production of a high grade matte.

The plant consisted of three blast furnaces of different dimensions, but averaging about 36 by 163 in. at the tuyeres, and 6 ft. 6 in. from tuyere-center to feed floor. The jackets were supported on a bed plate, and the tuyeres were placed about 13 in. above the level of bottom brick lining, giving a crucible of the depth mentioned. The furnaces were provided with sumps lined with fire brick, attached to the middle of their long side. Matte and slag discharged continuously through the sump into settlers, from which slag flowed continuously and matte was tapped periodically. The superstructure of the furnace was built unusually high, and each had a down-comer to a flue in which most of the dust was settled.

A system of wet recovery was in use also. The hot dry gases were drawn from the flue and treated in a scrubbing tower, where an additional recovery was made. The flue dust proper comprised 3.5 to 7 per cent of the ore treated and consisted of Ag, 14 oz. per ton; Au, 0.12 oz. per ton; Cu, 2.3; Pb, 3.5, and Zn, 7.1 per cent. The slime from the scrubbing towers comprised 2 to 4 per cent of the ore smelted and consisted principally of lead, gold and silver, and the object of recovery was its sale to lead smelters. It carried Ag, 16 oz. per ton; Au, 0.11 oz. per ton; Cu, 2.4 and lead (dry), 6.3 per cent.

Sampling was entirely by hand, a tenth-shovel portion usually being reserved when unloading shipments. The portion cut out for the sample was reduced in quantity and size, and finally the usual buyer's, seller's and umpire samples prepared. The balance of the sample was reserved until settlement had been made.

Smelting practice comprised two steps, preliminary smelting of the raw ore into a low grade matte, and further smelting of this product with silicious ores to form a matte carrying about 300 oz. silver per ton. Formerly mattes had been made carrying several thousand oz. per ton, but better saving was made with a lower concentration ratio. The final product contained 14 to 23 per cent copper.

The raw ore-charge contained about 14 to 20 oz. silver per ton, 2 to 3 per cent copper, and an excess of iron over silica or insoluble matter of from 8 to 15 per cent. Thus a charge consisted of 2600 lb. ore, 225 lb. lime rock, 1400 lb. slag from the concentrating furnace, 200 to 300 lb. flue dust, and 325 lb.

coke. About 65 per cent of the sulphur was eliminated on the first smelting. The concentration, based on net ore smelted and matte produced, was only 2.44 per cent. The slag from this operation was clean to be thrown over the dump.

The matte produced from the green ore-charge was re-smelted with silicious ores. The ore from the Commodore mine at Creede gave the best results, although some Leadville silicious ores were used even if leady. Cripple Creek ores were unsuited and gave sticky slags. The fuel consumption, based on net ore smelted, was about 14 per cent.

The capacity of the furnaces smelting green ore varied from 125 to 175 tons of net ore per 24 hours. On a concentrating charge from 225 to 300 tons of charge were smelted in the same period.

Electrolysis of Iron-Containing Copper Solutions.—*Metallurgie* of December 8, 1910 contains a short note on the use of revolving cathodes in the electrolysis of impure copper solutions, according to a process of F. Lacroix (German patent 225,652). Impure solutions containing only 1 per cent copper can be treated. The electrolyte containing ferrous salts is stirred up by rapid rotation of the cathode and is driven at considerable speed through a perforated anode by centrifugal force. The ferrous salts are changed at the anode to ferric salts and passed outside. This prevents the ferric salts from reaching the cathode where they would otherwise react with the copper deposited there. The electrolyte enters the electrolytic tank at a point btween the revolving cylinder cathode and the surrounding perforated anode. The cathode makes about 40 revolutions per minute. The anode solution is rich in ferric salts and these are passed into coke towers or similar apparatus where they are treated with the sulphurous vapors from the roasting process. The ferric salts are again reduced to ferrous salts with formation of sulphuric acid. The solution of ferrous salts is then taken again to the electrolyzer.

Tin.

Concentration and Reduction Works.—The production of ingot tin, 99.8 per cent pure, is reported from Mount Franklin, near El Paso, Tex., by Chas. A. Dinsmore, who contributes a description of the plant to the Dec. 31, 1910, issue of the *Mining Journal* (London).

Concentration is done by a combination of wet and dry methods. The ore is crushed and screened by the usual methods. The first concentration is by Harz jigs, the tailing from which is dried, reground, sized and treated on dry tables. Sizing for dry concentration is very important, and in this plant 10 sizes are made, from 20 mesh to 200 mesh, by means of the Keedy dry sizer. The work of the tables is reported to be excellent.

The tin concentrate is reduced in a reverberatory furnace, oil being used as fuel. The charge consists of one part pulverized anthracite coal and eight parts concentrate. Reduction requires from six to eight hours, and about one ton of concentrate can be smelted per day. Temperature attained, 2700° Fahr. Loss of tin from concentrate to ingot, about 0.5 per cent. The concentrate represents about 60 per cent of the original tin in the ore.

A Cornwall Plant.—In the *Journal* of the Chem. Met. & Min. Soc., of South Africa for October, 1910, C. F. Thomas has published the details of tin concentration at a plant in South Crofty, Cornwall. The crude ore is hand sorted and finally crushed through jaw crushers and stamps. The latter weigh 1065 lb., drop 7¾ in., 102 times per minute. Discharge 1¾ in. to 2¼ in., through 20-mesh gunmetal screen. This screen costs twice as much as steel screen, but lasts 5 days as against 36 to 48 hours for steel. Stamp duty, 2.8 tons per 24 hours.

The pulp is classified by Luhrig classifier into four products; the first three classes are treated on tables and vanners, the fourth, or slime, being settled and then treated on vanners. The concentrates are calcined in Brunton furnaces, 15 ft. in diameter. Capacity, 4 tons to 5 tons of concentrate to a sweet roast in 24 hours. Fuel consumption, 1000 lb. to 1200 lb. coal. The arsenic recovered from the calcination is sold crude.

Wetherill magnetic separators are used to clean the concentrate. The first separator has six magnets, the first two being used to remove iron and the other four to remove wolfram. The iron product contains about 3 per cent to 8 per cent cassiterite, very little of which is free. The wolfram product averages 40 per cent to 55 per cent tungstic acid, and is treated with concentrated sulphuric acid for from five to seven days, after which the residue is dried and again magnetically treated with the recovery of from 10 per cent to 25 per cent cassiterite. The non-magnetic cassiterite is easily cleaned for market. The current used on the separators is 110 volts, with 1.5 amp to 3 amp for the weak magnets and 10 amp to 14 amp for the strong.

Zinc.

Separation of Zinc from Vapors Containing Zinc Oxide.—According to *Metallurgie* of December 8 Paul Schmidt and Desgraz (German patent 225,956) proceed as follows: The vapor containing zinc oxide is passed through scrubbers of the usual type where the gases come in contact with the purifying liquid. The combination of water and soap solution did not give satisfactory results since the sulphurous acid generally contained in the vapors is absorbed by the water, soluble zinc salts being formed, and the zinc oxide dissolved. This new process therefore uses oil (crude petroleum, tar oil, etc.), as any zinc sulphate in the gases is insoluble in these solutions. The zinc oxide is separated and afterward freed from the oil by means of presses.

Aluminium.

Alloys and Impurities.—The *Giesserei Zeitung* of January 1, 1911, brings an article on aluminium alloys and impurities. The natural impurities of aluminium are silicon, iron, titanium, and the alkaline metals, sodium, potassium. Calcium and titanium are found very rarely and are easily extracted. Titanium has a good influence on aluminium favorably if it does not exceed 3 per cent. An aluminium alloy with 2 per cent titanium offers tremendous resistance to tensile stresses. Iron and silicon give luster to aluminium and make it hard. Sodium and all other alkaline metals are bad impurities in alloys poor in copper. They offer no resistance to the destructive influences of dampness and air. Aluminium bronze has from 7½ per cent to 10 per cent copper. Above 10 per cent alloys become brittle. Aluminium with less than 50 per cent zinc gives a non-crystallizing mixture of metals which is so homogeneous that the two metals cannot be recognized under the microscope. Nickel increases its elasticity. Magnesium-aluminium alloys do not resist the destructive influences as well as other alloys. They are expensive but very light. An alloy of this type contains Al 95.5 per cent; Mg. 1.50 per cent; Cu. 1.50 per cent; Ni, 1.50 per cent. Manganese and chromium increase hardness so that with 50 per cent chrome the aluminium cannot be worked. Tin in small quantities makes it fragile. The alloys of aluminium flow more easily than aluminium and it was tried to use them in soldering aluminium. But the tests were failures due to the great heat conductivity and oxidation of aluminium. Tungsten hardens aluminium and increases its resistance to any destructive influences.

Grinding.

Chilian Mills.—In Russia the Chilian mill is almost universally used to crush ores preliminary to amalgamation. Its use represents a slow development from the practice of crushing ores by spreading them on the main thoroughfares for carts and other vehicles to pass over. In *Bulletin* No. 75 of the Inst. of Min. and Met., London, Mr. H. C. Baylon traces the development of crushing in Russia and gives the results of present practice. The following tabulation gives a summary of the type of mills used in five typical plants.

	Plant No. 1	Plant No. 2	Plant No. 3	Plant No. 4	Plant No. 5
No. of Chilian mills in plant.	6	4	6	4	6
No. of runners per mill....	2	2	2	2	2
Diam. of pan across bottom.	7'6"	8'9"	8'2"	10'6"	9'4"
Distance between centers of runners	6'	6'9"	6'6"	8'3"	7'6"
Width of face of runner, in	10	10	10.5	10	12
Diameter of runner..	5'6"	5'6"	6'6"	5'6"	6'6"
Weight of runner, lb.....	5400	5400	5400	5400	108,000
Revolutions of mill per min.	12	14	13.5	12	11
Mean travel of runner per min	226'	297'	275'	311'	260'
Height of discharge, in.....	10	10	9.75	9.5	8
	Screen Used.				
	1 mm slot.	1 mm slot.	¼ to ⅛ in. punched.	1 mm slot.	1 mm slot.
Water to ore ratio, by weight.	10:1	6.5:1	7:1	13:1	..
Duty per 24 hours, tons....	16	26	20	19	24
Amalgam collected—					
from mills.....	86%	81%	83%	85%	..
from plates.....	13%	18%	16%	15%	..
from sundry sources....	1%	1%	1%	....	..

No accurate data on power is available, but it is estimated at from 7 hp to 12 hp per mill. The following sizing tests show the work of the mills.

1 mm screen	Plant No. 1 %	Plant No. 2 %	Plant No. 3 %	Plant No. 4 %
+30	0.2	0.4	0.2	0.1
+60	2.41	14.84	3.2	1.3
+100	14.72	22.06	12.80	11.0
—100	82.67	62.70	84.80	87.6

As the main object in view is to crush the ore very fine and to obtain the highest possible percentage of gold by amalgamation in the pan itself the results are excellent. The low capacity of the mill is due to the purpose for which it is used, and little change will be made as long as this factor remains the guiding principle in the milling practice of the country.

A pair of tires will serve for the crushing of about 9000 tons of ore and will weigh about 7800 lb. per pair when new and 1000 lb. per pair when discarded. Dies weigh 5000 lb. per set when new and about 2200 lb. when discarded.

Inside amalgamation is standard practice. Clean-up is made once a day, and 6 lb. to 8 lb. of mercury are added to the mill during the 24 hours. Outside hard plates are used and kept under locked covers. They are cleaned once a month.

Hand feeding is usually practiced, but the author describes a new mill for which he has provided an automatic belt feeder. The belt receives ore from a chute and is moved toward the mill a certain distance with each revolution of the runners. The device is automatic and increases or decreases the quantity of ore as needed.

The new Chilian mill, also devised by the author, which is used in connection with the automatic feeder, has runners 6 ft. in diameter, 1 ft. face and weighing 10,000 lb. It makes 14 r.p.m. to 16 r.p.m., the runners having a rate of travel of 340 ft. and 427 ft. In the mills running at 14 r.p.m. it has been found that a height of discharge of 9 in. to 10 in. and a water ratio of 4.5:1 to 5.5:1, with 1 mm screens, gives the best product and results. The wear of tires is from 0.62 lb. to 0.65 lb. per ton crushed, and of dies, 0.28 lb. The life of the slotted screen is about 1200 tons of ore crushed. The capacity of the machine is 42 tons per 24 hours.

The author believes that if the same amount of thought and attention were devoted to the development of the capacity of this type of Chilian mill as has been devoted to the heavy stamp-tube mill combination in South Africa it would prove a serious rival and give a product nearer to the ideal aimed at in that goldfield.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Blast Furnace Charging Apparatus.—With the object of regulating and evenly distributing the charge, and avoiding the abrasion of the inner wall of the furnace by the falling charge, Mr. J. B. McKennan, of Pueblo, Col., has devised the charging apparatus shown in the illustration, Fig. 1. A metal stock guide 1 with stock bell 3 and apron 3 form annular walls which guide the descending charge, causing it to fall in rings and preventing it from striking the wall of the furnace. The main stock hopper is shown at 5 and the receiving hopper at 8, the latter being closed by the bell 9. The distributing hopper 10 is provided with a spout 12, eccentric to its axis, and is designed to rotate above the receiving hopper. This movement

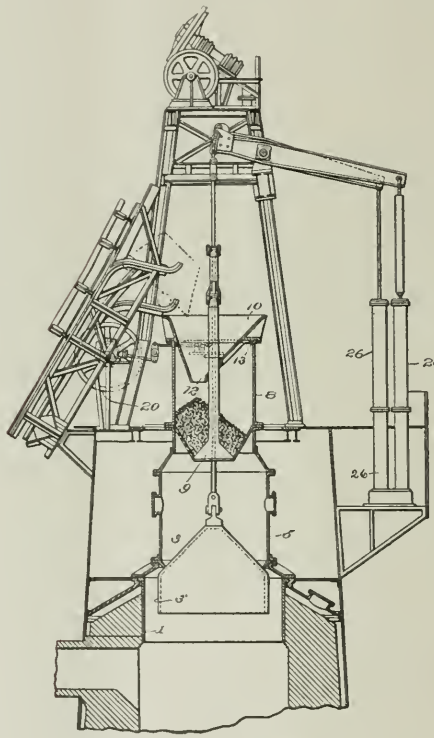

FIG. 1.—BLAST FURNACE CHARGING APPARATUS

is accomplished by means of rack and pawl mechanism connected with one of the sheaves 20 of the cable hoists.

In operation each skip load of material is delivered through the distributing funnel to the receiving hopper, as shown in the cut, the bulk of the charge being deposited eccentric to the axis of the hopper. The bell 9 is then lowered by the power cylinder 23, and the charge is deposited on the bell of the main hopper. The bell 9 is then closed again. During this interval another skip load is being hoisted and the funnel 10 has been shifted to another position, so that the eccentricity of the next load is different in position. Each succeeding load is advanced in position in a similar manner. In practice Mr. McKennan proposes to deposit nine skip loads of material in each furnace charge, six of coke, two of ore and one of limestone, preferably in the order mentioned. The distributing funnel will have seven positions and be moved two-seventh of a

revolution after each skip load has been deposited. Thus in seven furnace charges each skip load of the charge will have been put through the funnel while in each of its seven positions. After a full charge has been deposited in the hopper 5, the bell 3 is lowered by the power cylinder 26, and the charge falls through the annular opening formed by the stock guide and apron of the bell. (980,811, Jan. 3, 1911.)

Gold and Silver.

Agitator.—In the agitation of ore pulp it is desirable to have air valves which permit of flow in one direction only, so that should the air pressure be cut off for any reason, pulp cannot return into the nozzle. Such a nozzle is described in specifications of a patent granted to LOUIS T. SICKA, of Milwaukee, and assigned to the Allis-Chalmers Co. The details of the nozzles and their application to the bottom of an agitation tank, are shown in Fig. 2. There may be as many nozzles as desired, arranged around the bottom of a tank; one set projecting through the tank wall into the central well, and the other flush with the wall. In operation the set projecting into the central well cause the pulp to flow upward through it, and cause the agitation. The other nozzles are useful only in breaking up accumulations of slime or pulp when starting the agitator.

The pipe forming the nozzle 10 is capped at the end and perforated with a series of openings 11, which are larger at

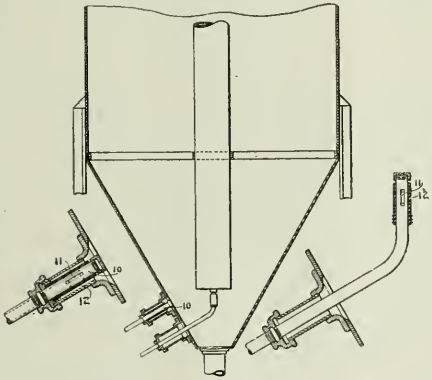

FIG. 2.—AGITATOR

the outer surface of the pipe. A piece of rubber tubing 12, is placed on the pipe over the openings, and fastened to the pipe at its lower end by cords. When air is forced through the pipes, it will press the rubber tubing outward and escape into the tank. If the pressure of air is cut off, the material above and outside of the nozzles will close the same and prevent the entrance of any foreign material. (978,667, Jan. 3, 1911.)

Suction Filter.—A continuous filter for cyanide pulp, which is also automatic in its action has been devised by HARRY E. KIER, of Colorado Springs, Col. The device is a circular rotary structure, upon which are mounted horizontal filter trays to receive and filter the pulp. In one revolution of the structure each tray is in turn brought into connection with suction for removing the cyanide solution, then wash water and suction to remove the weak wash solution, and finally with compressed air to loosen the cake and assist in discharging it when the tray is automatically dumped.

The filter is shown in vertical and horizontal sections in Figs. 3 and 4 respectively. As shown, there are eight filter trays 24, each connected by flexible hose with a set of pipes 51, 52 and 56, these being connected by means of valves 54, 55 and 56, with the circle tubes shown in the center of Fig. 4. The circle tubes have connections through the central hollow column with suitable pumps for creating vacuum or pressure. The pipe 51 is the suction pipe and is connected with suction pump 95; through it the first cyanide solution is withdrawn. The pipe 53 is a second suction pipe, connected with a suction pump 94, by means of which the weak wash solution is drawn off. The pipe 52 is the air pipe which delivers compressed air to the filter tray from a compressor, such as 96.

In operation the trays pass under a source of flowing pulp, as the pipe 47. After receiving a charge of pulp the valve

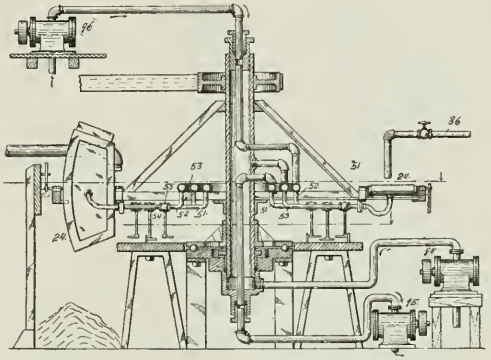

FIG. 3.—VERTICAL SECTION OF SUCTION FILTER.

connecting with the first suction pump is opened and cyanide solution drawn off. This suction continues until the tray reaches the wash water pipe 86, when it is cut off, and the cake subjected to a wash of water to remove the remaining traces of cyanide solution. From this point the valve connecting with the second pump is opened and the wash solution drawn off into a suitable receiver. Finally, the tray reaches

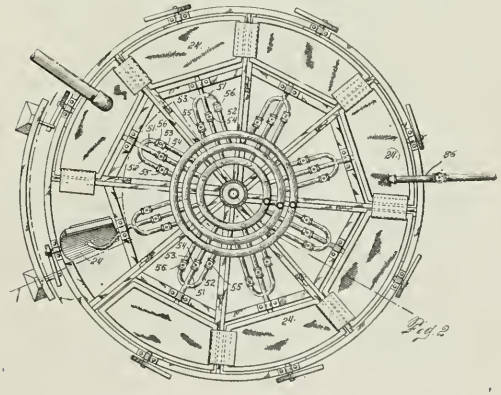

FIG. 4.—HORIZONTAL SECTION OF SUCTION FILTER.

a point where the suction is cut off and compressed air delivered into the filter tray under the cake, thus loosening it ready for discharge when the tray is dumped as shown in the illustrations. The action is automatic, the various valves being opened and closed by means of triggers mounted on the stationary platform 7, and engaging the stems of the valves as shown in Fig. 3. (978,381, Dec. 13, 1910.)

Copper.

Reverberatory Furnace.—In a patent recently granted to Messrs. W. J. MURPHY and A. E. CULLEY, of Butte, Mont., a new form of reverberatory furnace is suggested, the objects

being to provide a different method of feeding the charge, and a more efficient method of applying the heat. As shown in Fig. 5, which is a plan view, it is proposed to feed the charge at two constricted portions of the hearth area, through a system of hoppers and screw feeders, delivering the material at a point slightly above the level of the molten mass on the hearth. The inventors believe that this is preferable to dropping the charge in a mass from the top of the furnace. In

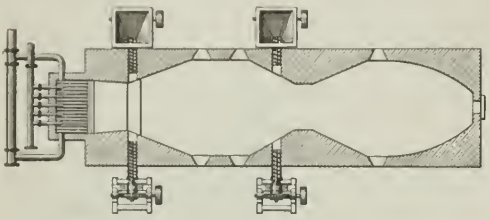

FIG. 5.—REVERBERATORY FURNACE.

applying the heat to the charge it is proposed to do away with the bridge, and direct the flame from the elevated fire-box, downward on the hearth of the furnace against the charge, by means of a series of jets of air or steam. (978,621, Dec. 13, 1910.)

Baggaley Process of Smelting.—Metallurgists will recall the experimental work of RALPH BAGGALEY, of Pittsburg, Pa., as carried on at the smelting works of the Pittsburg and Montana company at Butte, Mont. It was his intention to provide an inexpensive means for the direct treatment of gold, silver and copper ores, without preliminary concentration or other treatment, and thus avoid the losses incident thereto. Where such ores contained sufficient fuel to provide heat for smelting he added no carbonaceous fuel. His furnace was a converter-smelter, for the production of a low grade matte, which he afterwards enriched and converted by treatment with silicious ores, after the manner of the present practice of basic converting. The process was in operation for several months, but later abandoned. Metallurgists interested in knowing the details of Mr. Baggaley's ideas may find a very complete description in his latest patent specifications, numbers of which are given herewith. (977,922, 977,996, Dec. 6, 1910.)

Zinc.

Volatilization Process and Furnace.—An improvement in the metallurgy of zinc is the basis of a patent granted to HARRY H. HUGHES, of Springfield, Mo. In our issue for August, 1910, page 502, we gave some details of the furnace, which consists of a revolving cylindrical retort and condenser, with provision for keeping air from entering the apparatus. The feed is continuous, and spelter and residue are discharged separately. In a more recent patent granted to the same inventor, he provides a larger and stationary condenser in place of the small rotating one indicated in his previous patents. (980,640, Jan. 3, 1911.)

Furnaces.

A stirring device for mechanically rabbled furnaces has been patented by UTLEY WEDGE, of Ardmore, Pa. The illustration Fig. 6 represents a vertical cross section of the improved rabble arm and rabble. The stirrer arm is represented by 1', the rabble head by 3' and the rabble blade by 2. The rabble head rests on the stirrer arm, and is held in position while moving by means of the bent portion 4. The rabble head may rise to ride over any obstruction on the furnace hearth, the pivotal axis being near the point 4. Rabble arms may be interlocked on the arm by means of a tongue projecting from one into a recess of the other, as at 6. The rabble blades are made independent of the head, so that they may be removed when worn. They fit onto the head with a dove-tailed joint as shown. In order to prevent the corrosion of the stirrer arm it is provided with sleeves of refractory material as shown at 11. The advantages claimed by the inventor are the ease of removing any rabble head or blade, and the reduction in cost of the parts and of the roasting operation. Alternate forms of the interlocking rabble head, and of the method of applying the refractory sleeve, are shown in the specifications. (980,717, Jan. 3, 1911.)

Dust prevention in the discharge of roasted ore from a furnace, is the object of a device patented by THOMAS EDWARDS, of Ballarat, Australia. The machine consists of two or more cylindrical chambers mounted one above the other. A central rotary spindle extends vertically through these chambers, and carries a number of apertured discs which rotate in the bottom of each chamber. As the discs revolve they periodically register with openings in the bottom of each chamber and allow ore to pass to the chamber below; but the discs are so arranged on the spindle that the apertures in all the chambers are never open at the same time, so that the ore is discharged from the furnace in small quantities by a series of short drops. This prevents the dusting which is inevitable when large quantities of hot are discharged from a furnace. If desired the chambers may be water-cooled, and the ore thereby cooled for a subsequent operation. (979,937, Dec. 27, 1910.)

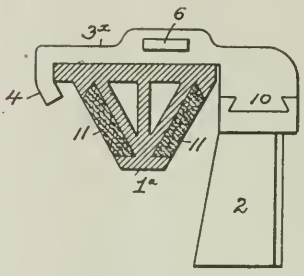

FIG. 6.—STIRRING DEVICE.

Granulating Slag.

A process for granulating molten slag recently has been patented in the United States by HEINRICH COLLOSEUS, of Berlin, Germany. It already has been proposed to granulate slag by allowing it to flow over a rotating drum having nozzles in its outer circumference through which liquid could be ejected for the purpose of assisting the granulating process, or for adding a desirable substance to the slag. The present inventor finds that the process is greatly facilitated by directing horizontal streams of fluid just beneath the flowing stream of slag and just as it falls on the revolving drum. (980,606, Jan. 3, 1911.)

Electrolytic Processes.

Chlorates and Hypochlorites.—In the production of chlorates and hypochlorites by chloride electrolysis without a diaphragm (as well as in other electrolytic processes) it is of importance to prevent the hydrogen bubbles set free at the cathode from sticking to it. For this reason Mr. FRANK H. BRIGGS of Elyria, Ohio, does not use a straight plate for cathode, but forms it with slanting sides so that the hydrogen bubbles detach and rise. For chlorate and hypochlorite production he uses a lead cathode coated with platinum. (981,371, Jan. 10, 1911.)

Persulphuric Acid.—In the past the production of persulphuric acid by electrolysis of sulphuric acid has been carried out by cooling the electrolyte below 10° C. and adding some hydrochloric acid to increase the yield. Dr. G. TEICHNER of Nürnberg, Germany, has discovered that no cooling of the whole electrolyte is necessary and that the addition of hydrochloric acid may be omitted, if only the anode is maintained at about 15° C. The electrolyte may be at a temperature of more than 20° C. He makes the anode hollow and passes water of 12° C. to 15° C. through it. He uses sulphuric acid of specific gravity 1.35, an anode of platinum, a cathode of lead and an anodic current density of 0.5 amp. per square centimeter. The electrolysis is carried out as rapidly as possible to avoid

the formation of Caro's acid which has a depolarizing action. This is effected by making the volume of the electrolyzed liquid as small as possible, for instance, 5 cu. cm to 10 cu. cm electrolyte for 1 amp. (981,900, Jan. 17, 1911.)

Cleaning Metallic Articles.—To clean articles of gold, silver and other metals from the tarnish of oxide and the like, Mr. H. E. GENET of New York City immerses the articles in a solution of hot sodium hydroxide and brings them in contact with a piece of aluminium, for instance, in form of a perforated aluminium dish. This represents a short-circuited galvanic couple and the oxide tarnish is reduced to metal. (980,627, Jan. 3, 1911.)

Mercury from Poor Ores.—To extract mercury from poor ores, Mr. BELA SZILARD of Paris, France, uses as lixiviating agent a mixture consisting of a hot solution of sodium chloride and of calcium sulphide obtained as a by-product in the manufacture of soda by the Leblanc process, or of other calcium sulphides rendered alkaline by oxide of calcium. The tepid mixture is added to the finely crushed ores, and after standing for two days a current of hot air is passed through the mixture from below. The calcium sulphide is converted into calcium thiosulphate which is deposited with the ores. The liquid discharged contains mercury not in the form of a sulphide but in the form of a double salt solution of mercury and sodium chloride which is submitted to electrolysis. Any silver contained in the ore is also dissolved and precipitated by electrolysis. The lixiviation is best carried out in an autoclave boiler at a pressure of four atmospheres. (980,364, Jan. 3, 1911.)

Electric Furnaces.

Ferroboron.—To produce carbon-free ferroboron for use in the steel industry, Mr. C. A. HANSEN of the General Electric Company, Schenectady, N. Y., uses silicon as reducing agent. The mineral colemanite $Ca_2B_6O_{11}.5H_2O$ is first dehydrated by heating to a temperature of 450° C. It is then powdered and mixed with powdered ferrosilicon (since this is cheaper than pure metallic silicon). Sufficient silicon must be added to reduce all of the boron. The powdered mass is mixed with a suitable binder, like waterglass, and pressed into pellets. The pellets are heated in an electric furnace to a temperature above 2000° C. The silicon reduces the boron and is itself oxidized to silica which combines with the calcium to form a slag of calcium silicate which separates perfectly from the metal matrix. (982,135, Jan. 17, 1911.)

Pure Metals.—Pure tungsten, tantalum, vanadium, etc., are produced by Mr. WM. C. ARSEM, of the General Electric Company, by reduction in his vacuum tube furnace. The reducing agent is very finely divided carbon, produced from lampblack by heating to a very high temperature in a vacuum or by graphitizing. (979,363, Dec. 20, 1910.)

Carbon Electrodes.—In the manufacture of large carbon electrodes, Mr. WALTER GASTON of New York City proceeds as follows to prevent them from cracking. The electrode as it comes from the baking furnace hot is plunged into boiling tar and pitch so as to impregnate it thoroughly. The pores are thereby filled. The operation really adds a second binder to the electrode. The absorption of moisture during storage and transportation is thereby avoided. The addition is stated not to impair the conductivity, but rather to improve it. (979,465, Dec. 27, 1910.)

Carbon Electrode.—In the manufacture of very large amorphous carbon electrodes, such as are now used in electric steel furnaces, considerable difficulties are experienced in baking them uniformly. Mr. RAPHAEL H. WOLFF, of New York City, proposes to overcome this difficulty by making the electrode essentially of two pieces, an exterior and an interior. The exterior part is hollow, for instance, a cylinder, the inner hole being wider at one end than at the other. This hole is then filled either with one solid piece or a combination of pieces, and tar pitch is infused to bind the whole together. (974,008, Oct. 25, 1910.)

Recent Progress in the Electrometallurgy of Iron and Steel.

A two-ton Roechling-Rodenhauser electric combination induction furnace is to be erected by the American Electric Furnace Company of New York some time during this year at Lansdowne, Pa. This is the first furnace of this type to be installed in this country.

The Girod furnace installed by the Simonds Manufacturing Company at Chicago is now being transferred to their new and modern plant at Lockport, N. Y., and will be used for producing and refining the high-grade steels required for their saws, machine knives, files, etc.

Interesting information comes in reliable private reports from Europe. Amorphous carbon electrodes are there in successful use in steel furnaces in sizes up to 600 mm (24 in.) diameter. In commercial practice with European Heroult furnaces the consumption of these carbon electrodes is from 3 kg to 4 kg per ton of steel. A new 20-ton to 22-ton Heroult furnace—the largest in size so far—is soon to be erected in a German works. In another German works using the Heroult furnace (seven tons capacity) the energy consumption (with fluid charge) is given as 105 kw-hours per ton of steel.

From Messrs. C. W. Leavitt & Company of New York, the American representatives of the Girod furnace, we have received the following data on the experience of the Cockerill Company in Seraing, Belgium, who have been operating a 4-ton to 5-ton Girod furnace for the past two years and are refining molten Thomas steel for rails, locomotive tires, cannons, automobiles, etc. The total cost of power, labor, furnace upkeep, electrodes and general expenses for the operation of this electric furnace is given as less than $4. The Krupp firm in Essen is installing a 12½-ton Girod furnace to be operated by three-phase currents.

* * *

As to the reduction of iron ore in the electric furnace interesting information comes from Scandinavia.

The large 2500-hp electric shaft furnace at Trollhättan was put in operation in November and appears to work perfectly well. The furnace was first tapped on Nov. 16, and from a private report written two weeks later we learn that the furnace had been working without difficulty since the start, and especially that none of the electrodes had been touched in that time.

From another report, dated Dec. 10, it is learned that the furnace had been running continuously since Nov. 15 and was working quite satisfactorily.

The furnace plant is equipped with apparatus for making gas analyses and taking temperatures at every 3 ft. of the whole stock. There is also a very elaborate laboratory for testing the raw materials and the product obtained.

The yield was for the first week 2090 kg (6578 lb.) per hp-year, but has since been raised to above three metric tons (about 6600 lb.) per hp-year.

The consumption of coal amounted to 24 hectoliters to 26 hectoliters (85 cu. ft. to 92 cu. ft.) per 1000 kg (2204 lb.) of iron.

The works are not permitted to be examined by outsiders at present. But all on the spot, even previous enemies of the system, are reported to be enthusiastic over the undertaking.

At Domnarpoet, when the first electric iron-ore smelting experiments by this system took place, a new furnace for from 4000 hp to 5000 hp is at present under erection. It is expected to be ready for operation in May.

At Tyssedal, Hardangen, Norway, there is an installation of two electric shaft furnaces, each for 3500 hp, one of which will be put in commission next summer.

The Aktiebolaget Elektrometall, in addition to the foregoing, has given licenses to several other works, one of which is the Uddeholms Iron Works in Sweden, for which they are now preparing drawings for three furnaces of 3000 hp each.

Heating Liquids by Direct Steam.

In this article a description will be given of some appliances, made by the Schutte & Koerting Company, of Philadelphia, for heating liquids by means of direct steam.

Fig. 1 shows a continuous water heating device. The steam enters at *S* and the water at *W*. Heating is effected by the mixture of steam and water taking place through nozzles in the instrument. *D* is the discharge.

This apparatus may also be used as a condenser and as an exhauster for heating coils and on the exhaust pipe of engines. It can be used with steam of any pressure or with exhaust steam for the maintenance of a partial vacuum, or as an exhauster for the removal of air only. The capacity and range in volume is regulated by the central hand wheel, and when used for heating water the temperature is regulated by throttling with a valve in the steam pipe.

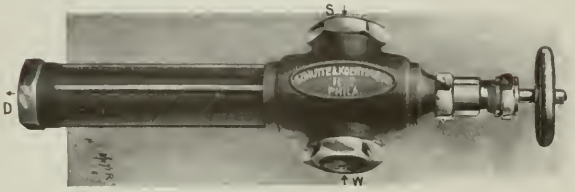

FIG. 1.—CONTINUOUS WATER HEATER

Fig. 2 shows the use of the attachment for the production of hot water. The water is supplied from the bottom, the steam from the top. Valve *B* is a stop valve in the water supply pipe, while the volume of the water is regulated by the spindle *A*. The temperature is regulated by throttling with valve *C* in the steam supply. This valve can also be used as a stop valve in the steam pipe, but it is more convenient to provide a separate lever valve *D* for turning on and shutting off the steam. To start, the water is first turned on at *B* and then the steam turned on at *D*. To stop, the steam is first shut off at *D* and then the water shut off at *B*.

Fig. 3 shows an attachment to an engine exhaust or heating coil. In this attachment it is necessary to have a check valve *E* to prevent a back flow of water, and also a free exhaust valve *F* is required. The discharge is run free to waste or all or part of it into a hot water tank for use.

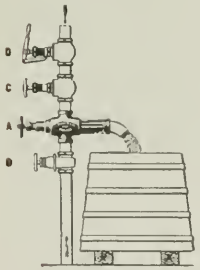

FIG. 2.—ATTACHMENT FOR PRODUCTION OF HOT WATER.

Fig. 4 shows the application of this continuous water heater for making warm water in different stories of buildings. The installation is very simple. *S* being the steam pipe, *P* the water pipe, *H* the heater.

The continuous water heater offers a means of heating the water exactly to the desired temperature, the regulation being obtained by the steam spindle.

The circulating heater, Fig. 5, does satisfactory work when water need not be heated above 160° and where steam pressure is not less than 35 lb. This circulating heater, within the above limits of temperature and pressure, works without noise or nearly so, and works very economically. *S* is the steam inlet, *D* the discharge of the hot water.

The disturbing noise and destructive effect on open tanks, when steam is introduced into the water through perforated pipes, is entirely obviated by attaching the noiseless heater to the end of the steam pipe. The heater discharges in the form of an inverted cone, offering a large surface and thus causing rapid condensation (Fig. 6).

If water is to be heated to a temperature not exceeding 165° Fahr. the air inlet on heater is closed with a plug and nothing but the heater is needed, as it will be noiseless with any pressure of steam from 5 lb. to 100 lb. and above. If water is to be heated to a temperature above 165° Fahr. and up to boiling point, then an air pipe must be attached. The purpose of this pipe is to permit air to be supplied to the discharge jet and by its admixture prevent the formation of steam bubbles which otherwise in rising to the surface would escape and collapse and thus cause the noise. Thus water is heated in less time and with less expenditure of steam than could be done by the use of a perforated pipe. The air is drawn in through the action of the heater if the steam pressure is proportionate to the depth of the water in the tank above the apparatus, viz:

Height of water above heater or depth of tank in feet	3	4	5	6	7	8
Minimum steam pressure, in pounds	4	8	12	18	24	32

Thus under the above conditions the heater will work without noise up to any temperature by the addition of the air pipe, which is best fitted with a cock or valve. The heater works also with exhaust steam. Fig. 7 shows an installation.

Bureau of Standards Analyzed Samples.

The following announcement of the Bureau of Standards in Washington, D. C., will be of interest to chemists and metallurgists at large.

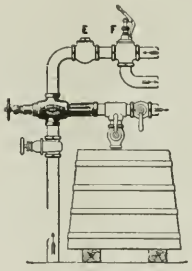

FIG. 3.—ATTACHMENT TO ENGINE EXHAUST.

The Bureau of Standards is ready to supply the following new analyzed samples:

No. 29, titaniferous magnetite ore from New Jersey.

No. 11a, basic open-hearth steel with 0.2 per cent carbon.

No. 12a, basic open-hearth steel with 0.4 per cent carbon.

The steels replace the original samples which are exhausted. Renewal samples of Bessemer steels with 0.1 per cent and 0.2 per cent carbon are in process of analysis, also a nickel and a chrome-vanadium steel.

The Glasgow Smoke-Abatement Exhibition.

By John B. C. Kershaw.

The Glasgow Smoke Abatement Exhibition, which was recently held in the Victoria Skating Rink in that city, has been an unqualified success, the attendance having averaged over 4000 persons per day, and a large amount of business having been obtained by the exhibitors as a direct outcome of their displays of smoke-abatement appliances.

The exhibition was promoted by the corporation of the city, and the three sections into which the exhibition was divided were under the charge of the leading officials connected with the gas, electricity and sanitary undertakings of the city. The success of the exhibition was no doubt largely due to the rivalry between the gas and electricity sections of the exhibition as to which should have the better display.

This combination of gas and electricity appliances under one roof is a new feature in smoke-abatement exhibitions, and the success of the Glasgow exhibition indicates that it is one worth imitating. There is no doubt that where, as in Glasgow, both the gas and electricity supply undertakings are owned and worked by the municipality a joint exhibition of cooking and

heating appliances can be easily arranged and can be made very attractive to the general public.

In their prospectus the promoters of the exhibition state "that for a considerable time the Corporation of Glasgow has been devoting much attention to the problem of air purification, recognizing how necessary an unpolluted atmosphere is to the mental and physical well-being of the community. Special committees have gone into the subject with extreme care—reports have been prepared by experts—and numerous experiments have been made and the results recorded. From these it is clear that the question of smoke abatement is a vital one in towns. Having regard to this fact the corporation has decided that it would be most desirable to bring before the citizens of Glasgow and the west of Scotland, in a practical and interesting fashion, the latest and most scientific devices in connection with smokeless heating and lighting, embracing the most up-to-date methods and contrivances for the complete combustion of fuel, as well as the most modern developments in heating, lighting and ventilation by means of gas and electricity. The readiest means of interesting the public in these matters is to hold an exhibition which will bring before them in a concrete form the advantages to be gained and the economies to be effected by the adoption of recent discoveries; and the corporation has accordingly entrusted to a special committee the organization of such an exhibition."

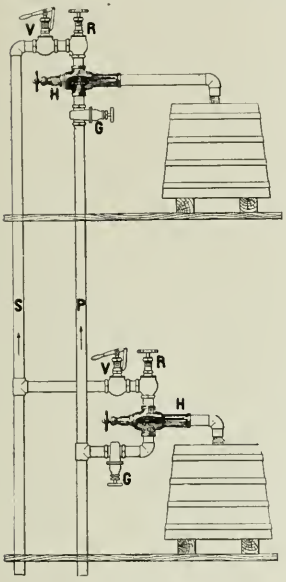

FIG. 4.—PRODUCTION OF HOT WATER IN DIFFERENT STORIES.

The appliances and materials exhibited at Glasgow related chiefly to the domestic smoke problem, and only a few of the exhibits dealt with the abatement of the smoke arising from the furnaces and steam boilers used in manufacturing operations.

FIG. 5.—CIRCULATING HEATER.

The exhibition was divided into three sections, the largest and most important being that devoted to the display of gas lighting, heating and cooking appliances. The second section was devoted to the use of electricity for similar purposes, and the third section was given up to exhibits of smokeless fuels and of patent stoves and grates.

The most important and striking exhibits in the first two sections were the model houses in which every lighting, heating and cooking appliance was operated in the first case by gas and in the second case by electricity.

In some of the smaller Scotch towns the gas committees are now installing gas grills, stoves and meters free of charge, it having been found that this free gift of gas heating appliances pays the corporations by the increased sale of gas. The gas committee of the Glasgow corporation is contemplating a similar step and when this is taken the electricity committee is almost certain to follow in their footsteps. With electricity at 2 cents per kw-hour and gas at 50 cents per 1000 cu. ft. the cost of lighting and heating one's house by either gas or electricity in these Scotch towns need not be prohibitive; and when the public has become accustomed to the comfort and convenience of the newer methods of lighting and heating the days of the coal-fired open grates will be numbered. Already there are stated to be 80,000 gas cooking appliances in use in Glasgow alone, and their use is extending.

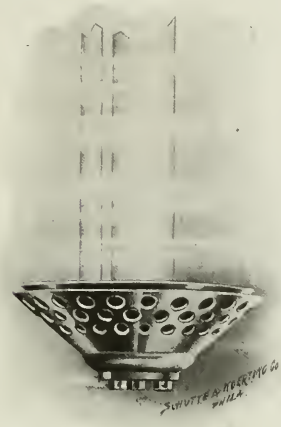

FIG. 6.—CONE DISCHARGE.

In Section II of the exhibition a wonderfully varied and attractive display of electric lamps and heating appliances was shown, and here again it would be invidious to single out any special firm's display for mention in this report. The exhibit of electric radiators and of cooking appliances was probably the best that has yet been collected in the United Kingdom and there is no doubt that the Glasgow Electricity Undertaking will have a largely increased day load as a result of the 1910 exhibition. It may be stated here that in Glasgow it is proposed to supply electricity for heating from the lighting circuits, the amount consumed being calculated from the total current registered by the meter, and the average lighting consumption in previous quarters. All above the average lighting consumption is charged at 2 cents per kw-hour and is assumed to have been used for heating purposes. By this system the expense of separate wiring and meters is avoided.

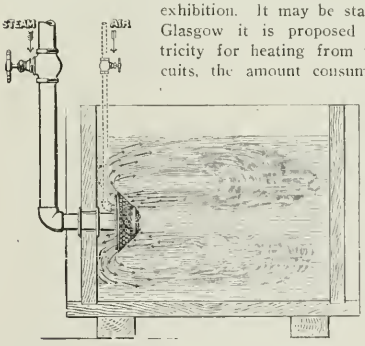

FIG. 7.—CONE DISCHARGE INSTALLATION

The smokeless fuel and patent grate and stove section of the Glasgow exhibition was the smallest of the three and attracted less public attention than the other two for reasons which are obvious, since electricity and gas lend themselves in numberless ways to the creation of striking and attractive exhibits. The smokeless fuel exhibits comprised peat from the

Glasgow distress committee's works at Palacerigg; anthracite from the Scotch and South Wales coal fields; coke, "charco," "coalseld" and "coalite."

The three last are patented smokeless fuels, with a limited sale in the United Kingdom.

"Charco" is made by subjecting ordinary coke or partially carbonized coal to a special treatment before cooling, as it comes from the gas retorts or coke ovens. It ignites readily, burns steadily and gives out greater radiant heat than either coal or coke, while being absolutely smokeless.

"Coalseld" is a similar fuel, produced from ordinary gas-coal by use of a modified form of gas retort. It is now being made at the Glasgow Corporation Gas Works, and sample orders are being supplied by the gas department of the city.

"Coalite" is coal carbonized at a low temperature (700° Fahr.) and supplied by the British Coalite Company, whose main works are at Barking, near London. It is unfortunate that the company producing coalite has not so far been a financial success, and that in the north of England it is practically impossible to purchase this fuel for trial purposes.

The improved grates and stoves at the Glasgow exhibition were chiefly of the well-known and widely used types, the only novelties being open grates fired on the under-feed principle, which has been successfully used for boiler firing. These grates have been placed on the market by the White Flame Fire Company, of Stirling, and depend for their action upon the partial coking of the raw coal before it reaches the well of the grate. A hopper at the back of the fire contains the day's supply of fuel; this hopper is closed with a sliding gas-tight cover.

The coal is heated and partially coked in this hopper, and the hydrocarbon gases can find no outlet except through the opening into the grate, where they are consumed as they pass through the glowing fuel. The solid fuel is raked forward through the opening of the hopper as required to replenish the fire.

The makers of this grate do not claim that it is entirely smokeless, since when the fire is first lighted it labors under the disadvantages of the ordinary open fire as regards imperfect combustion and smoke production. But when the fuel in the grate and the hopper behind it have once attained their maximum temperature the fuel is smokelessly consumed, while all the advantages of the ordinary open fire, good ventilation and cheerfulness, are retained.

The show of smokeless kitchen stoves for use with ordinary coal was also a good one. In these the conditions required for smokelessness are more easily attained, since most cooking stoves are now designed on the closed-in principle and only require scientific design to obtain perfect combustion of the fuel. In one of the kitchen stoves exhibited at Glasgow the combustion chamber of the stove is extended under the hot-water boiler, and the hot gases then pass under the hot plate and oven before escaping to the chimney. By this arrangement it is claimed that double the amount of hot water is obtained, with a saving of 50 per cent in fuel.

The use of glass for the doors of ovens and plate-warming chambers is another novelty found in some of the kitchen stoves exhibited by J. C. Parker & Company, of Glasgow, and attracting some attention.

A large number of anthracite and coke stoves were exhibited by various well-known makers, and there is no doubt that the popularity of the former for heating offices and rooms is widely extending, since they require little attention and are most efficient heating appliances.

The Glasgow exhibition, although confined to only one branch of the problem of smoke abatement, namely, that of "domestic smoke," has been, as regards attendance and results, more successful than the Smoke Abatement Exhibition held at Sheffield early in 1909, and its organization and management will probably prove the model for the succeeding exhibitions of this character which are certain to follow.

NOTES.

Chemists' Club.—The new home of the Chemists' Club is making very satisfactory progress and is rapidly nearing completion. The laboratory floors and the public stairway will be completed by February 1. Over half of the available laboratory and office space has already been rented.

The American Rolling Mill Company, of Middletown, Ohio, has just completed a splendidly equipped research laboratory costing approximately $40,000. The excellent organization which the company is known to have, has recently been strengthened by securing the co-operation of Dr. A. S. Cushman, of Washington.

The Hardinge Conical Mill Company have removed their offices from 35 Wall Street to 50 Church Street, New York City.

New Electrolytic Furnace Process for Metal Production.—On page 688 of our December issue mention was made of a patent of Mr. J. W. Beckman, of Niagara Falls, Ontario, for producing pure carbon-free metals and their alloys from their oxides and sulphides. The process is applicable to a great number of metals, since only those are excluded which are more electropositive. We learn that among other metals, vanadium and titanium have been produced by this process on a laboratory scale. The process depends upon the fusibility of a salt composed of CaO and the oxide of the metal to be produced. This fused salt provides a cheap electrolyte in which the oxide is dissolved and electrolyzed. On account of the high boiling point of this electrolyte, the metals, even those with a comparatively high melting point, can be deposited in a molten condition and the operation is very simple on this account.

The Stuart & Peterson Company, of Burlington, N. J., have sent us their new catalogue No. 219, which contains on 176 pages illustrations and concise descriptions of the many products of their manufacture, including plain and porcelain-lined ware, steam-jacketed kettles, hollowware, chemists' appliances and specialties, furnaces, heaters, vacuum pans, retorts, tanks, etc.

Calendars.—The Goldschmidt Thermit Company, of New York City, have sent us their pretty calendar for 1911 with a map of the United States and some interesting illustrations of thermit welds. The attractive calendar of the Lead Lined Iron Pipe Company, of Wakefield, Mass., has a fine picture of the new Pennsylvania Railroad Terminal in New York City, which contains over 100,000 feet of lead-lined iron pipe for hot and cold water, made by that company.

The Arizona Copper Company produced for the month of November, 1910, 1505 tons of copper.

The Bureau of Mines, Washington, D. C., has recently published two bulletins, Nos. 2 and 3, of the new series. They deal respectively with North Dakota Lignite as a Fuel for Power Plant Boilers, and The Coke Industry of the United States as related to the Foundry.

Bakelite.—Information No. 1, issued by the General Bakelite Company, 100 William Street, New York City, gives first a brief outline of what bakelite is and of the properties of bakelite C and liquid bakelite A. Then follow brief chapters on bakelite lacquer, bakelite protective enamels (for the protection of metallic surfaces, pipes and machinery against corrosion), bakelite-impregnated wood, bakelite adhesive cement (for joining iron, wood or other hard materials with a cement, which, after hardening, can withstand moisture, steam, alkalies, acids, solvents and heat), bakelite plastic mixtures, bakelite paper and bakelite-asbestos paper. The pamphlet, which is exceedingly neat, is concluded by directions for molding bakelite paper and other bakelite plastic mixtures and by a description of the bakelizer which is the apparatus for heating under increased atmospheric pressure to convert bakelite A and B into bakelite C.

Hardening and Annealing.—We have received from Mr.

C. U. Scott, of Davenport, Ia., his illustrated catalog on gas-blast furnaces, fuel gas plants, hardening furnaces for high-speed tool steels, tempering furnaces, annealing furnaces, etc. Mr. Scott acts as a consulting engineer for the heat treatment and hardening of steel, besides the manufacturer of furnaces and gas plant for this purpose. This firm also undertakes hardening of tools made from carbon or high-speed steels, also case hardening and heat treatment of steel in general.

Messrs. **Merck & Co.**, manufacturing chemists, of New York City, with works at St. Louis, Mo., and Rahway, N. J., announce the removal of their headquarters to 45 and 47 Park Place, New York City, on Jan. 1, 1911.

A Flux for Brazing Metals, notably cast iron, is composed of potassium cyanide, one part by weight, and borax glas, two parts. The pieces to be brazed are heated to redness, when the flux is applied and the parts immediately become cleansed and reduced. A brazing solder, such as Hungerford's No. 24, may then be applied with success. The flux mentioned was made the subject of a patent by W. W. McIver, of New York.

The **T. L. Smith Company,** Milwaukee, has issued a new catalog describing the Symons crusher. The Symons is a gyratory which is lighter and more compact than the usual form of this machine. The upright shaft is stationary, and the motion is imparted to the crusher head by means of an eccentric sleeve which revolves on the shaft.

Symons Brothers, Chicago, have recently designed a new disc crusher, not a grinder, which is said to have extraordinary capacity. It reduces rock or ore to ⅛ or ¼ in. and is designed to have a place in stage crushing. The manufacturers have issued a descriptive bulletin.

Camp Bird, Ltd., owning the Camp Bird mine at Ouray, Col., and the Santa Gertrudis property in Mexico, is prosecuting work at the latter in anticipation of the forced abandonment of the former within a year or so on account of exhaustion of ore. Developments at the Santa Gertrudis indicate that a modern mill will be erected, comprising stamps, tube-mills, cyanide tanks, filter presses, precipitation presses and appurtenant machinery. The plant will have a capacity of 600 tons per day. The November report of the company shows that the Camp Bird mill crushed 6577 tons of ore, producing 6218 oz. of bullion and approximately 723 tons of concentrate. The balance applicable to profit was $98,500.

The Arizona Copper Co. produced in the month of December, 1910, 1612 tons of copper.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in October, 1910, was 71. The total tonnage milled during that period was 1,916,801 tons of ore; 9756 stamps were in operation with an average duty of 7.31 tons per 24 hours. Tube mills in commission numbered 188. The yield for the month was 653,147 fine ounces gold. The statement shows a great advance over the same period for last year.

Evaporator Patent Suit.—The patent suit of the Kestner Evaporator Company versus the American Evaporator Company has recently been decided in favor of the defendant. The decision is written by Judge Holland. Infringement was claimed of patent 548986 of Oct. 28, 1895, of Peter Cooper Hewitt; the claim in question reads as follows: "In an evaporator provided with heating tubes and one or more return tubes, a separating chamber provided with a series of stationary tangential nozzles communicating with the heating tubes, substantially as specified." In the defendant's evaporator a film of liquid travels along the inner surface of the heating tubes under the influence of a vacuum to an upper chamber where the vapor is given a circular motion and the particles of liquid separated from the vapor by centrifugal force, after which the vapor passes off. But since the liquid is not returned for retreatment through "one or more return tubes," as the liquid passes once through each effect only, the above mentioned claim is not found to be infringed.

Gold pannings obtained in the field may be preserved for assay by using lead foil, 4 in. square, into which the values are washed after panning. The foil is bent into basin shape, and after receiving the washings, which are drained off, may be rolled up and marked with a number or letter. The gold is then in shape for cupellation, if very clean, or for fusion if mixed with much silica. The process avoids the possibility of loss or salting, and is suggested by Mr. J. E. Wood in *Bull.*, No. 75, I. M. M.

Solubility of Oxygen in Molten Silver.—Spitting and foaming of molten silver at the time of solidification and blistering of solid silver when it is rolled are due to dissolved oxygen. F. G. Donnan and T. W. A. Shaw recently determined the solubility of oxygen in molten silver and presented their results to the Soc. of Chem. Ind. They devised special apparatus and ascertained that the volume of oxygen (measured at 0 mm and 760 mm) dissolved in 10 g melted silver at 1020° C. and 751 mm pressure is 20.5 ccm. To combine with this quantity of oxygen 0.03 g of aluminium would be required to be mixed with each 10 g silver.

The Sulitelma Company, operating in Norwat, produced in the month of September 760 tons of copper concentrate by the Elmore process.

La Rose Consolidated Mines Co., operating in the Cobalt district, Canada, gives the following information relative to the milling of its low-grade ore, covering the period from Sept. 8, 1909, to May 31, 1910:

Average assay crude ore	28.58 oz. per ton.
Average assay tailing	3.68 oz. per ton.
Tonnage treated	18,423.56 dry tons.
Concentrate produced	628.02 dry tons.
Contents of crude ore	526,581.00 oz.
Contents of concentrate	416,629.59 oz.
Average assay of concentrate	663.00 oz. per ton.
Actual extraction	79.12 per cent.
Ratio of concentration	29.3 to 1
Net value of concentrate	$199,569.70
Cost of concentration	$61,351.54
Profit on low-grade ore	$138,218.16

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines for the month of August, 1910, was 72. Tonnage milled, 1,884,288; number of stamps dropping, 9685, with an average duty of 7.15 tons per 24 hours; tube mills in commission, 182. Comparison with last year shows fewer stamps and more tube mills at work, a larger tonnage treated, increased working cost per ton milled and decreased working profit. The yield for the month was 649,269 fine ounces, being larger than for any month in 1909 or 1910.

The Utah Copper Co. has issued its tenth quarterly report covering the third quarter of 1910. During July all three of the concentrating plants were in operation, but at the end of that month the Copperton plant, at the mine, was closed permanently and dismantled. The equipment is being used to remodel the Arthur plant at Garfield. The improvements at the Magna plant are completed and that plant is now treating in excess of 10,000 tons per day. When the Arthur plant is remodeled on the plans corresponding to those of the Magna plant it will have a capacity of about 6000 tons. The tonnage milled for the quarter was less than that for the preceding quarter, on account of the changes being made in plants as indicated. The production was 23,194,921 lb. of copper as compared with 25,124,052 lb. for the second quarter. The total net profit for the quarter was $1,329,966.88, from which a dividend of $1,168,882.50 was paid. The average cost per pound of copper produced, after smelter deductions were made, was 8.25c. as compared with 7.53c. for the preceding quarter. The increased cost of production is ascribed to the decreased tonnage treated. The average copper content of the ore was 1.5 per cent for the quarter and 1.4 per cent for the month of September.

Personal

Mr **W. H. Aldrich,** late managing director of the Consolidated Smelting & Mining Company, of Canada, is to have a voice in the management of two of the large Western copper companies, the Inspiration in Arizona and the Mason Valley in Nevada. His headquarters will be at Los Angeles.

Mr. **A. J. Bone** has been appointed smelter superintendent of the Copperhill smelter of the Tennessee Copper Company.

Dr. **Regis Chauvenet,** formerly president of the Colorado School of Mines, is at Mount Franklin, near El Paso, Tex., where he is engaged in tin mining and smelting.

Mr. **N. H. Darton** has been appointed geologist for the new Bureau of Mines. He has been connected with the United States Geological Survey for many years.

Mr. **Forrest Goody** has been in Denver for some weeks preparing plans and specifications for a metallurgical enterprise in Nevada.

Mr. **G. W. Heintz,** general manager of the United States Smelting, Refining & Mining Company, Salt Lake City, recently returned from a trip of inspection of the new baghouse system Company of Canada, with headquarters at Trail, B. C.

Mr. **Victor G. Hills,** Denver, investigated some tungsten deposits in Nova Scotia last month.

Mr. **Martin E. Hiltner,** Deadwood, S. D., is to have charge of the metallurgical opeerations of the New Reliance Mining Company, of South Dakota. He was recently in Denver purchasing supplies for the mill.

Mr. **Ernst Leitz,** of Wetzlar, Germany, the famous manufacturer of microscopes, etc., has received from the University of Marburg the honorary degree of Doctor of Philosophy, in recognition of his services rendered to science by having constructed for more than fifty years instruments of highest scientific value.

Mr. **Jay Lonergan,** Colorado School of Mines, '05, has accepted a professorship in the Imperial University, Tientsin, China, and has left Denver for his new field.

Mr. **R. H. Stewart** will succeed Mr. W. H. Aldrich as managing director of the Consolidated Smelting & Mining Company of Canada, with headquarters at Trail, B. C.

Mr. **A. H. Wethey,** who for many years has been in charge of Senator Clark's interests in Butte, retired from his position on Jan. 1. Senator Clark has disposed of so many of his former interests that the retention of a general manager is unnecessary.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ELECTRIC FURNACES (*Continued.*)

698,980 and 698,981, April 29, 1902. Johann Lühne, of Aachen, Germany.

Combined arc and resistance type. Material for making glass is melted by electric arcs and further heated by solid resistors. The melting apparatus is a trough-shaped receptacle having two flat vertically grooved side walls converging downward, jacketed with kieselguhr, ashes or glass wool. The negative electrode is a horizontal carbon bar, square in cross-section, extending from end to end of the trough near its bottom. It is hollow and perforated, and hydrogen, or a mixture of hydrogen and air, is supplied through it, being burned in the furnace to assist in melting the material. A series of horizontal positive carbon electrodes passes through each side of the melting chamber, their ends being in proximity to the angular sides of the negative electrode, and arcs being sprung between them and the negative electrode. The molten product passes down through a valved opening onto an inclined hearth. This hearth either contains resistors consisting of solid electrolytes, e. g., oxides of beryllium, calcium, zinc or titanium, or is composed of such materials containing embedded metal terminals. No current passes through these resistors, or resistor hearth, until they are heated by the descending molten material, or by hot air. As the molten glass passes over this hearth the light impurities derived from the electrodes are removed by a skimmer, or retained by a depending partition. The glass thence passes through a series of concentric annular chambers, partially separated by partitions or dams.

699,333, May 6, 1902, A. Ludwig, of Bernburg, Germany.

Arc type, for heating materials in an atmosphere of highly compressed hydrogen or other gas, e. g., for the production of artificial diamonds. The chamber is a thick metal tube, closed at the lower end and surrounded by superposed flat metal rings. The cover is a massive plate of metal, secured on the open end of the cylinder by a metal strap consisting of a series of plates bolted together. Opposed wedges are driven between the strap and cover. For very high pressures the strap is heated before the wedges are tightened. Th wedges may have division lines to regulate their position and the pressure of the cover on the cylinder. The gas pressure may be several thousand atmospheres. The electrodes are vertical carbon rods, one extending up from the bottom of the cylinder and the other depending and adjustably carried by a revoluble spindle journaled in the cover. A gas inlet pipe also passes through the cover. The spindle and pipe may be held by wedges.

699,654, May 13, 1902, Guillaume DeChalmot, of Holcomb's Rock, Va. Assignor to the Willson Aluminum Company.

Arc or resistance type, for reducing ores, or producing carbides or silicides. The furnace is a pot of iron lined with carbon, consisting of a lower and an upper section. It is mounted on a truck. The lower section has a tap hole for metal and may have one for slag. The upper section has a gas outlet. The pot constitutes one electrode; the other one is a depending carbon bar or group of bars. The furnace has a flat top made of closely interfitting hollow sections of cast iron, cooled by water circulated through them. Several electrodes may pass through openings in the cover. The electrode or electrodes and cover are maintained at the same potential by an electrical connection. The electrodes pass through stuffing boxes consisting of plates adjustably secured to the cover, with a packing of asbestos fiber. The cover is insulated from the pot by a 2-in. luting of brick, with or without clay or mortar. After the run the product or slag may be solidified in the pot and removed in one piece by first lifting off the upper section. Each electrode may carry 1000 or more amperes and may be independently switched into or out of circuit.

700,808, May 27, 1902, William R. Parks, of Chicago, Ill.

Arc type, especially for the production of calcium carbide. The furnace is a pot with brick sides. The lower negative electrode is a slab of carbon set in the floor of the pot, having a circular gutter leading to a central opening and drain. The positive electrode is a tube, vertically slitted and depending into proximity to the carbon hearth. The charge materials are delivered by a hopper and conveyer into the closed upper end of this electrode, and may be preheated therein by gas injected by pipes extending through the side of the electrode

701,218, May 27, 1902, Fausto Morani, of Rome, Italy.

The furnace is a shallow pot, receiving a depending electrode. The pot has a water-cooled metal base, or imbedded water pipes. The depending electrode is a square bar, or

group of bars, carried by water-cooled metal yokes. The terminals are also water-cooled and are clamped against flat faces of the bars. The taphole is a slit in a hollow water-cooled casing of steel. The product is tapped into a water-cooled metal pan. May employ several electrodes supplied by polyphase current.

701,986, June 10, 1902, E. G. Acheson, of Buffalo, New York.

Eelectrode and terminal for furnaces, consisting, as shown, of 72 horizontal square carbon bars, piled in contact, with a copper plug screwed into the end of each bar. A vertical copper plate is bolted to these plugs and has a marginal flange with openings, into which are soldered the terminals of the flexible cables, preferably of the same number as the carbon bars. Seventy-two graphitized-carbon electrodes, each 4-in. square, will carry a current of 37,500 amp. A receptacle to contain water is bolted to the plate flange, and is connected to an insulated reservoir.

702,081, June 10, 1902, A. Voelker, of Ehrenfeld, Germany.

Resistance type. Material for the manufacture of glass is intimately mixed with graphite or powdered charcoal, about 10 per cent, to give a conductive mass which serves as a resistor. Saltpeter is also added to eliminate the carbon as carbon dioxide. Pure carbon is necessary, and the ash slightly colors the glass. The carbon may be replaced by conductive oxides or metals, e. g., "brownstone," or powdered iron or silver. These are only suitable for the production of colored glass. A continuous or alternating electric current may be used.

BOOK REVIEWS.

Metallography. By **Cecil H. Desch,** D. Sc., Ph. D., lecturer in metallurgical chemistry in the University of Glasgow. 429 pages, 14 plates, 108 diagrams. Price, $3. New York: Longmans, Green & Company.

This is probably the most satisfactory book yet written on this subject in English. The treatment throughout is clear and free from the mysterious phrases of other treatises. It is comprehensible from beginning to end by any bright, industrious person, and will give a clear understanding and good foundation in the subject. Numerous references to original literature are given; the microphotographs are excellent. It is really a treatise on the physical and chemical properties of metals and alloys.

* * *

Elementi di Metallurgia. I: Siderurgia. By **Alfonso Greco.** 192 pages, 27 illus. Price, 1.50 lire ($0.45 retail price in New York). (Students' Library Series.) Livorno (Leghorn): Raffaello Giusti.

The characteristics of almost all Italian books, aside from their contents, are clear type, good paper, and wonderful cheapness. The equivalent of such a book as this in English would not be sold for less than $1. The metallurgy of iron as here set forth is elementary and slightly antiquated, about the equivalent of Bauerman's small English text-book, edition of 10 years ago. It can do good service in the Italian technical schools, however, for giving students their first ideas of the subject.

* * *

An Introduction to the Study of Metallurgy. By Sir **W. C. Roberts-Austen.** Sixth edition, revised and enlarged by **F. W. Harbord.** 478 pages, 189 illustrations. Price, $6 net. Philadelphia: J. B. Lippincott Company.

Mr. Harbord has given this well-known text-book a new revision and has improved it in many respects. His revision of Chapter III—the physical properties of the metals—is not altogether satisfactory, much valuable fundamental information being still omitted, such as many of the boiling points, all the latent heats of fusion and latent heats of vaporization. The claim that Siemens was the progenitor of the electrolytic furnace (page 111) is very far-fetched, and detracts from the reliability of the work as a whole. The chapters on pyrometry and metallography are practically new and well done. The chapter on fuels has been much enlarged on the descriptive side, but on the side of calorific powers and calorific intensities it is still as wofully deficient as in former editions, viz., at least 20 years antique. The chapter on thermochemistry of metallurgical reactions has been improved a little, yet it needed a great deal more.

Altogether, the book is now a mixture of good, fairly good, and pretty bad; brought up to date in spots and back in the last century in others. We confess to being disappointed with the general effect; we had hoped that the revision would be altogether thorough, satisfactory and up-to-date throughout Perhaps we expected the impossible; at any rate, we certainly hoped over-much.

* * *

Testing for Metallurgical Processes. By **James A. Barr.** 216 pages. 22 illus. Price, $2. San Francisco: Mining & Scientific Press.

A commendable book for use in research and metallurgical laboratories. Very practical directions are given for the use of the instruments and appliances useful in metallurgical testing and the handling of the data obtained, so as by calculation to reach further conclusions and results, is clearly set forth. In the calibration of pyrometers the variation of the boiling points of water and sulphur with barometric pressure should have been given, and the melting point of copper should be specified as 1084° in a *reducing* atmosphere. The treatment of the subject of fluxing and slags is particularly good.

The book is recommended to students of metallurgy and to those who, by practical work, are trying to master for themselves the principles of metallurgical processes.

* * *

Tables for the Determination of Common Rocks. By **Oliver Bowles,** M. A., instructor in geology and minerology, University of Minnesota. 16mo., 64 pages. Price, $0.50 net. New York: D. Van Nostrand & Company.

The author says: "Rocks can never be learned from a text-book alone." We will go further than this and say: An abridged text-book such as this, is of practically no assistance under any circumstances in *learning* rocks. If you know the rocks, the book can serve simply as an *aide de memoire,* if you do not know the rocks, it is of no assistance whatever in helping to know them. The compilation is occasionally somewhat careless; for instance, the red, bluish and green plagioclase feldspars are left out of the list of rock-forming minerals.

The publishers should be scored for putting 84 pages of advertisements in a book having only 64 pages of text. It is a rank imposition on the man who is supposed to carry the book around with him.

* * *

Elementary Crystallography. By **W. S. Bayley.** 239 pages, 311 illus. Price, $2. New York: McGraw-Hill Book Company.

This book, Part I of a general system of mineralogy, and published as a separate volume, is designed to introduce the reader to the subject of crystallography. Only a slight knowledge of physics, chemistry, and mathematics is required to comprehend the concise and generally well-written and profusely illustrated text.

But to the reviewer the work lacks one essential element in the presentation that unfortunately is missing from all modern books on this subject—that is, an adaptation of the usual academic presentation to practical use. Ninety-nine per cent of all students of crystallography intend to apply it only to the recognition of mineral forms, and there drop it. The presentation of the crystal forms as geometrically symmetrical solids does not assist in this practical application of the sub-

ject, and the use of the ordinary wooden models but little more. What is wanted is a work that gives more detail to the description of the non-geometrically symmetrical crystal forms as they actually exist—that is, the presentation to the student of the forms having missing planes and the crystals of unequal growth, in fact, of the crystal forms as they are usually found and not as the crystallographer thinks they should be. For instance, the author defines a cube as a solid consisting of six planes, each a *square* at right angles to the isometric axes. The actual number of square planes on the average crystallographic cube is rarely more than two, and later on illustrations are given of two cubes with but two square planes each. The author is not consistent in this regard.

The use of Naumann's symbols for indicating crystallographic forms is rather obsolete, all authoritative works on mineralogy and chemical crystallography using Miller's indices. Similarly, the terms used to name the various forms should have their more common synonyms given, as found in such standard works as Dana.

The chapters of Physical and Chemical Crystallography are welcome additions to an elementary book and are in keeping with the general plan of the more extensive chapters on Geometric Crystallography. The introduction of these chapters alone makes the work a notable improvement over any previous book of the same grade.

The M. C. C. Periodic Chart of the Elements, with introduction. Price, folded and bound, 8s. 6d.; roll form, 12s. 6d. London, W. C. (333 Grays Inn Road): The Metals Composition Company.

This is a chart 40 in. wide by 34 in. high, having on it 120 spaces 2 in. x 4 in., representing a periodic arrangement of the elements. For each element is printed in the space its principal chemical and physical properties. In the vacant spaces are printed condensed physical and chemical tables and other miscellaneous information. Ten groups of elements have been used, instead of the familiar eight, the distinction arising from making three groups of Mendeleeff's group VIII. The chart is clear, and will be of considerable interest in the chemical lecture-room or laboratory, hung up on the wall for casual reference.

Part I of the instruction is a straightforward and sensible explanation of the principles of the periodic classification of the elements; part II is a dissertation on "the periodic law and its relation to speculative thought." The latter part is distinctly out of place in connection with the educational aspects of the chart, for it deals with such philosophical abstractions as "Life: a Mystery" and "Universal Ultimate Relationship." It shows a wide range of solid reading and thinking on the part of the author, but the proper place for its presentation would be to read it before some philosophical society and see what would be the judgment of his peers upon his speculations.

Altogether, and considering by whom it is printed, it has such a tincture of the commercial and the alchemistical as "queers" it when we try to take it most seriously. Nevertheless, the chart may be found quite convenient and useful.

* * *

The Modern Manufacture of Portland Cement. By **Percy C. H. West.** Vol. 1, Machinery and Kilns. Price, $4 net. New York: The McGraw-Hill Book Company.

The manufacture of cement has increased in the past decade by leaps and bounds in this country, and Germany especially. The evolution from the old hand-raked reverberatory to the shaft kiln has been concomitant with the increasing uses of cement in the building trades. While text-books on the testing of cement and on concrete construction, especially reinforced concrete, are numerous enough in recent technical English publications, yet the practical and commercial side of making cement has been neglected. This we opine is due to the rapid flux which cement practice has undergone in the past ten years.

Accordingly it will be seen that this book of Mr. West is written at a moment when changes have become less and less noticeable and a standard of practice, or rather an approximate to a standard, has been obtained. Though the book in our opinion does not give due credit to the work of earlier American pioneers and to recent American pioneers as Edison, with the long rotary kiln and his pneumatic system of separation of the fines, yet the very fact that it does give prominence to the heavy and substantial machinery of the English cement works—a substantiality that often approaches mechanical corpulency—makes the book valuable to the American engineer, whose tendency is rather to a maximum of efficiency for a short period.

In the succeeding volume we hope that the application of physical chemistry to the practical problems of cement making and the question of thermal efficiency of the various systems, for each of which this journal is ever a constant advocate, will be discussed in the fullest proportions.

* * *

Outlines of Chemistry. A text-book for college students. By **Louis Kahlenberg,** Ph. D., professor of chemistry in the University of Wisconsin. 548 pages, 155 illus. Price, $2.60 net. New York: The Macmillan Company.

Why do our students spend so many years studying a foreign language and know so little of it at the end? Because they are troubled with the rules of good grammar before they can read or speak the language. Why do so many students know so little about real chemistry, although they "have been through" a chemical course? Because they have been pestered with theories and speculations before they knew the simple fundamental facts of chemistry, and the result has been to kill their proper interest in chemistry as an *observational* science.

We think Professor Kahlenberg exactly right when he puts only experiment and observation into the first five chapters of his splendid book, excluding from them even all reference to any theories whatever. This is the way to provide the student with facts to think about, to stimulate in a healthy way his curiosity, which gradually develops, as to what explanations there can be for these facts. This is the normal and natural way to acquire knowledge of theory; not to have it pumped into the observer just as he is acquiring his fundamental facts or even before he gets them. It is only after a student has tried to imagine for himself some rational explanations for the facts he has observed that he can properly understand, appreciate, and assimilate theory presented to him by others.

With these principles to start with and building thereon a system of instruction in elementary chemistry which is marked throughout by its appeal to the student's observing and reasoning powers (as to oppose a system of cramming into him a flood of facts mixed with cut-and-dried theoretical explanations) the experienced author and teacher has given us a wonderful book. There is only one other which we can compare it with—Mendeleeff's classical "Principles of Chemistry," and it is better than that for the purpose it is intended to serve—a one-year course in chemistry. Mendeleeff's work would need at least two years to work through, and is not so well arranged for the very beginner in the science.

The long experience of Professor Kahlenberg shows itself on almost every page of his book. It is clear, tactful, even sympathetic in places, in dealing with matters not easy to comprehend. The facts are carefully systematized, theories are skilfully introduced and presented in a larger-minded way, and the total result is a "work of art" in instruction in elementary chemistry which has probably no equal and certainly no superior.

We predict that our American educators will quickly appreciate the merits of this book and that it will have a phenomenal success.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. IX. New York, March, 1911 No. 3.

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

239 West 39th Street, New York.

The New Chemists Building

Elsewhere in this issue the program will be found of the exercises with which the new Chemists Building at 50-54 East Forty-first Street, New York, will be opened on March 17 and 18. For chemistry in America history has been made in the old cozy clubhouse in West Fifty-fifth Street and with it are connected dear reminiscences of many a glorious achievement and many a happy hour enjoyed in good fellowship. Now the old spirit is to be transplanted into the new big and magnificent home. This is the meaning of the opening exercises. The new Chemists Building is a grand monument representative of the united democracy of American chemists. A graceful and thoroughly practical twentieth-century structure, it has been erected, without outside help, to represent the ideals of American chemists. Our hopes and wishes are comprised in the old Saxon miner's greeting: "Glückauf."

Continuous Copper Converting.

Some years ago we pointed out in these columns the essential difference between a continuous and an intermittent process. This was to the effect that continuous operation was advantageous when the end desired was a large tonnage eliminating impurities cheaply and that an intermittent operation was advantageous when the end desired was a refined or semi-refined product of a definite nature. In short, a continuous process makes for quantity of product and an intermittent process makes for quality of product. For the complete elaboration of this principle the reader may be referred to our Volume III, page 90.

Copper converting is peculiar because it is at once a roughing metallurgical action and a finishing metallurgical action. As it unites two functions in an operative manner it is efficient. But at the same time it has the inherent disadvantages of an attempt to do two things at one time. These peculiar disadvantages are the cost of lining the converter, the amount of power used for furnishing the blast and the danger of loss of values by rapid driving. The lining is before first blow from 20 in. to 24 in. thickness, and, as everyone versed in the metallurgy of copper knows, is made of a plastic silicious material. The lining furnishes the silica for the slag produced by the oxidation of the iron in the matte blown up to blister copper. It is certainly crude to use the lining of the converter as a flux and seems as foolish as nature would if we lived on the inside of our stomach. But like many other processes crude from a theoretical standpoint, it nevertheless, is a practical process, for it works.

Various attempts have been made to use a lining that is basic and hence refractory to the ferruginous slag made. Professor Baggaley made some exhaustive large-scale tests with a basic-lined converter about five years ago at Butte, Mont. Prior to that time Mr. George Westinghouse had conducted a long series of experiments at Pittsburgh and later at Ely, Vt.

For commercial reasons alone both these attempts were never followed out. Indeed, in the several fat years of the metal industry, from 1900 to 1907, improvements were not needed as much as they are now in the present times of diminishing returns.

During the past year large-scale commercial demonstration of a basic-lined copper converter has been made by Messrs. Smith and Pierce at Ely, Nev. Also that enterprising concern, the International Nickel Company, has started work at Copper Cliff, Ontario, on a basic bessemer plant for working up the 30 per cent copper-nickel matte to an 80 per cent matte suitable for smelting by the Orford process. In both these attempts the silica is thrown on the slag continuously, but the tapping of the slag and the blowing are performed intermittently.

It might be argued that the logical process is rather to make the entire smelting process continuous and to do the final refining and the production of the copper anodes in an electric furnace, and it is interesting to give briefly the argument in support of this view. The operation of blowing up a 50 per cent matte to blister copper produces an active scorifying slag that will dissolve to some extent either a magnesite or a chromite brick or tamped basic lining. Oxide of iron, especially when a small percentage of iron sulphide is dissolved with it, is about as corrosive material at high temperatures as is well known. Indeed, oxide of iron can play the rôle of an acid with the formation of ferrates. The proper way, of course, is to use a stationary furnace or converter and water-cool the shell. From a theoretical standpoint this is ideal. Like pyritic smelting and "blast roasting" of sulphide ores the heat balance sheet shows that when once the operation is started at a good rate there is a fair excess of heat generated over heat lost by radiation so that the right conditions can be held uniformly. If this is possible in an intermittent operation there should be no reason why it should not be attained in the right form of a continuous apparatus.

Of course, there is a large proportion of slag—on the average 50 per cent of the original charge—that must be handled. Naturally this is a difficult proposition and regard must be paid to this difficulty. But the great success of the Dwight-Lloyd roasting and sintering apparatus is due to the continuous nature of the process which is conducted in it. It is naturally desirable that continuous copper-converting be done in large units. This would give the operation a sufficient excess of heat so that conditions could not change easily. It is, of course, patent that some means must be used to bring the oxygen of the blast continuously in contact with a large surface of matte. The difficulty and painful slowness of making blister copper out of "white metal" in the old-fashioned reverberatory furnace lay in the fact that the slag protected the matte from the oxygen. Possibly the old Nichols and James reaction of roasted copper-matte on copper-matte with the formation of blister-copper would be applicable. For the final finishing reaction and the removal of the gases nothing can be better or cheaper than the arc-type of electric furnace. The experience in the metallurgy of steel proves this.

We are not indulging at all in prophecy, but only attempting to judge the future from the past. Of late we have seen the great increase in the use of continuous blast-sintering machines in roasting sulphide ores and the extending use of the reverberatory smelting furnace for fine concentrates and flue-dust. Now we see the basic-lined converter. It is at least not illogical to expect the continuous converter in the not far distant future.

Some Interesting Rail Production Statistics.

Statistics of rail production in the United States in 1910, as just presented by the American Iron and Steel Association, show that the year was the next best in the history of the rail trade, the 3,634,029 gross tons produced falling short of the record year, 1906, by 343,858 tons and exceeding by 375 tons the production in 1907, which had stood as the second best year.

Such wild forecasts are sometimes made of the prospects of rail demand, and such curious views seem to prevail in many quarters as to the uses to which our rail production is put, that a cursory review of the general position may be profitable. There was in existence in the United States at the beginning of 1910 in the neighborhood of 400,000 miles of track, laid in steel rails. There was about 350,000 miles of steam railroad track, the remaining 50,000 miles of our estimate covering electric and other public roads using steel rails and industrial tracks. The tonnage of rails in this track can only be approximated, but was probably not far from 50,000,000 tons, which would be sufficient to lay 400,000 miles of track with 80-lb. rails. Up to that time there had been produced in the United States about 60,000,000 tons of steel rails, of which about 2,750,000 tons were by the open-hearth process. In the early years there were heavy imports of steel rails, while in late years there have been heavy exports, and these balance roughly. The deficit of some 10,000,000 tons represents, very roughly, the tonnage which has worn out. The total tonnage produced includes some material which passed through the mill twice, having worn out in service and being rerolled to pass through service again.

It may be of interest to observe, *en passant*, that there was produced in the United States a total of a little more than 10,000,000 tons of iron rails, and a small portion of that tonnage survives, there being at the beginning of 1910 about 8800 miles of steam-railroad track still laid with iron rails, involving, with the iron rails surviving in mines and other industrial plant, well in excess of 500,000 tons.

The fact that the tonnage of steel rails worn out in the United States has been in the neighborhood of only about 10,000,000 tons should assist in dispelling the curious view which is evidently entertained in some quarters that the chief use to which our rail production is put is the replacing of rails which have worn out in regular service. That is not the case. Even of the rails which have become unfit for service a large part has not yielded under proper usage, but has required replacement because too light for the much heavier service now involved. Had it been the case that the rail production of 10, 15 and 20 years ago was required to make up for the wearing out of rails, the present demand would be enormous, for the freight ton-mileage of the country—the only statistical measure we have of the service put upon rails—has approximately doubled each decade.

While there are no precise data as to the mileage of new

track laid in 1910 data are available which support an estimate of approximately 10,000 miles, which if laid in rails averaging 85 lb. per yard would involve about 1,335,000 tons. Exports amounted to 353,180 tons, while of light and standard rails used for industrial purposes the quantity may be estimated at about 250,000 tons. This would leave 1,696,000 tons for all other purposes, the summary being as follows:

	Tons.
10,000 miles steam track	1,335,000
Industrial uses	250,000
Exports	353,180
All other	1,696,000
Total production	3,634,029

The balance found by difference, 1,696,000 tons, must cover rails used for trolley and other transportation lines outside of steam roads, probably about one-third of the total, the balance being the tonnage used by the steam roads for replacement purposes. The major part of this is now ordinary replacement, but a portion represents the replacement of light sections which cannot stand up under the heavy duty imposed by high speeds and heavy cars and locomotives.

A few of the railroad systems present statistics of the tonnage of rails used for replacement purposes. By analyzing these statistics it may be shown that, very roughly, a ton of rails is worn out for every 250,000 ton-miles of freight traffic. The factor is only an approximation, but has value when there is practically no other indication. The total freight ton-mileage of the country in 1907 was 233,137,000 and in 1909 it was 227,199,000, so that a rough-and-ready rule is that when rails are of section sufficient to escape abuse, and meet only legitimate wear, the steam roads of the country are wearing out about 1,000,000 tons a year.

The study of rail statistics merely for the purpose of ascertaining where the rails go can have only an academic interest. We have made this little study for a more serious purpose. In the past rails have been used chiefly for laying new track; in the future they will be used more and more for replacing other rails which have worn out. The period of greatest railroad building is past; as far back as 1887 occured the greatest building of new road in a year, and while there remains a great deal of double-tracking to be done the laying of new track cannot be expected to increase much, if at all. The tendency to wear rails out, however, increases steadily. As already observed, there has been, approximately, a doubling of the ton-mileage of freight movement every decade and while this rate of increase may not be continued, there is certain to be increase at some rapid rate.

A rapid increase in freight movement and a slow increase in track mileage obviously involve an increase in the density of traffic on given stretches of track, and we have merely expressed, in terms of the entire railroad system, that which is common knowledge as to individual railroads. As the traffic increases and the rails are subject to greater and greater annual wear, the annual sinking fund necessary to replace the rail increases. It would be a simple matter to write an algebraic formula to illustrate the principle we wish to emphasize, but this form of expression is not necessary. It need merely be remarked that when the wear on rails was light, and they accordingly lasted a long time, it did not profit railroads to pay a given premium to obtain a more lasting rail, because the premium would increase the annual interest charge, while with a long life even the poorer rail would require but a small sinking fund to provide for its ultimate replacement. As the wear upon rails becomes greater and their prospective life is shortened, the annual sinking fund increases and it becomes more and more desirable to use a better rail, gaining more in decreasing the annual sinking fund for ultimate replacement than is lost by increasing the interest charge.

Thus, while a few years ago the railroads were interested merely in getting a fairly good and a safe rail, now those with the greatest density of traffic are anxious to obtain a very durable rail and are willing to pay a premium in order to secure it. We stand at the threshold of a great development in the manufacture of special steel rails. Only for 1909 and 1910 are there statistics of production of special rails. These statistics are as follows. They are quoted as given, though it is not clear why a distinction should be made between titanium and ferrotitanium steel rails:

1909.	Gross Tons.
Titanium	35,945
Nickel-chrome	12,287
Nickel-steel and electric	1,464
Manganese	1,028
Total	50,724

1910.	Gross Tons.
Titanium	195,408
Electric	4,210
Ferrotitanium	532
Manganese	390
Nickel, chrome and vanadium	81
Total	200,621

Of the 1909 tonnage of special steel 35,699 tons, or 70 per cent, was made from Bessemer steel, while in 1910 the proportion was 87 per cent. We are not prepared to draw positive conclusions from the statistics. They are suggestive, but perhaps of negative rather than positive conclusions. The high percentages of Bessemer rails treated may mean that open-hearth rails are regarded as "good enough"; at any rate they show that as to the refining action of titanium (the "titanium rail" is not a titanium alloy steel, but a steel purified by titanium, the titanium compounds formed passing into the slag) the Bessemer metal can be treated satisfactorily. The practical disappearance from 1909 to 1910 of nickel-chrome indicates a loss of interest in this alloy. The electric steel rail showed a large percentage increase, and 4210 tons of electric steel rails produced in 1910 furnishes at least a foundation for observation, being enough to lay more than 30 miles of track. The "titanium rail" shows a remarkable growth, from 35,945 tons in 1909 to 196,000 tons in 1910, and it is regrettable that the statistics do not indicate precisely the nature and extent of the treatment to which the tonnage was subjected. It was not until 1907 that as large a tonnage of open-hearth steel rails was produced, yet the open-hearth steel rail was regarded as a factor and was provoking a great deal of discussion.

Program of the Opening of the New Chemists Building in New York City

The celebration of the opening of the new Chemists' Building, 50 to 54 East Forty-first Street, New York City, will take place on Friday, March 17, and Saturday, March 18.

On Friday, March 17, there will be a reception at the new club building from 3 to 6 p. m.

The opening exercises in the auditorium under the auspices of the Chemists' Building Company will take place from 3:30 to 5 p. m.

In the evening a meeting will be held in the auditorium under the auspices of the New York Section of the American Chemical Society, which will begin at 8:30. After an introductory address by the chairman, Dr. Charles Baskerville, papers will be presented by Prof. R. B. Moore, of Butler College, Indianapolis, on the rare gases of the atmosphere and by Dr. Jacques Loeb, of the Rockefeller Institute for Medical Research, on the characteristics of living matter from the physico-chemical point of view.

On Saturday, March 18, a session will be held in the auditorium from 10:30 to 12:30 under the auspices of the New York Section of the American Electrochemical Society. After an opening address by the chairman, Mr. E. A. Sperry, papers will be presented by Dr. W. R. Whitney on mental catalysis and by Dr. E. F. Smith on recent developments of electro-analysis.

In the afternoon a session will be held from 2 to 4 p. m. under the auspices of the New York Section of the Society of Chemical Industry.

After an introductory address by the chairman, Dr. Charles F. McKenna, papers will be presented by Dr. Charles F. Chandler on the history of chemical industry in New York City and by Dr. W. P. Mason, of Troy, N. Y., on the contributions of chemistry to sanitation.

In the evening a subscription banquet will be held at the clubhouse under the auspices of the Chemists' Club.

On Sunday, March 19, there will be in the afternoon, beginning at 4 p. m., a concert by the Olive Meade Quartet.

Owing to the limited accommodations admission to all functions will be strictly by cards and tickets. Ladies are invited to attend all the functions with the exception of the banquet.

American Electrochemical Society

The nineteenth general meeting of the American Electrochemical Society will be held in New York City on April 6, 7 and 8 (Thursday to Saturday).

A special feature of this meeting will be the fact that it will be the first convention of a national chemical society to be held in the new beautiful Chemists' Building in New York.

The full program of papers, excursions and social functions will be printed in our next issue.

International Congress of Applied Chemistry of 1912.

The organization of the Eighth International Congress of Applied Chemistry, to be held next year in this country, has now been completed and will shortly be made public. The dates of the congress have been fixed as follows:

The opening meeting will take place at Washington, D. C., on Sept. 4, 1912 (Wednesday). The other meetings, both business and scientific, will be held in New York City, beginning Friday, Sept. 6, 1912, and ending Friday, Sept. 13, 1912.

The President of the United States will be the patron of the congress. Dr. Wm. H. Nichols is the president, Dr. E. W. Morley the honorary president, and Dr. B. C. Hesse, 25 Broad Street, New York City, is the secretary of the congress.

American Institute of Chemical Engineers

The third semi-annual meeting of the American Institute of Chemical Engineers will be held at Chicago, Ill., from June 21 to 24 (Wednesday to Saturday).

Arrangements will be made to visit a number of the large technical plants in the vicinity. The committees on chemical engineering education and on standardization of boiler tests will have important reports to present.

The Western Metallurgical Field.

Leadville's Celebration.

Probably no more unique celebration was ever held than that which marked the so-called rejuvenation of Leadville by the discovery of zinc carbonate and silicate. The event was combined with the annual celebration of Robert Burns' birthday, although there is no direct connection between the Scotch poet and smithsonite or calamine other than that the Leadville miners are interested in both.

The novel feature of the celebration consisted in a noonday dinner served to about 300 guests in a stope of the Wolftone mine, 850 ft. underground. The Western Mining Company, Mr. S. D. Nicholson, president, was the host of the occasion. The guests were taken down the shaft and through lighted drifts to the banquet-room. The latter was a stope from which about 3000 tons of 33 per cent zinc carbonate had been extracted and shipped to smelters. It was brilliantly lighted and decorated with flags and national colors, and the whole effect was such as to dispel the idea of being underground. In the evening a more elaborate and pretentious banquet was served at the Elks' Club, at which the significance of the recent discoveries were considered.

The largest problem which lies ahead of Leadville, and one of the most importance in connection with the zinc discoveries, is the future treatment of low-grade ores carrying from 10 per cent to 20 per cent zinc. There is a vast quantity of such ore which, at present, can not be handled. The lowest grade material yet shipped at a profit is 20 per cent zinc, and there awaits professional fame and ample reward for the metallurgist who shall devise successful means of treating the lower-grade ores. It is a significant fact that coincident with the discoveries of Leadville's new zinc resources many eminent metallurgists are working on the problem of cheap and more efficient zinc reduction, and there can be no doubt that some process will be devised for local application which will make profit for both miner and metallurgist. It is also significant that Leadville mining men are proceeding at once in the search for suitable processes for low-grade ores without postponing such action to the day of reckoning which inevitably comes when the high-grade and easily treated ores have been exhausted. Although no definite announcement can be made, it is known that already negotiations are proceeding between the mine owners and metallurgists who believe that they can solve the problem.

Some Interesting Company Reports.

The Utah Copper Company has issued its report for the fourth quarter of 1910. The work of remodeling the Arthur plant to conform to the system adopted in the Magna plant is progressing satisfactorily, and the first remodeling unit will be placed in commission at once. The production of copper for the quarter was as follows:

October	7,582,219 lb.
November	7,468,915 lb.
December	7,137,585 lb.
Total	22,188,719 lb.
Average monthly production	7,396,239 lb.
Total production for 1910	89,019,511 lb.

The average net cost of copper produced for the quarter, after smelter deductions were made, was 8.227 cents per pound, as compared with 8.25 cents for the preceding quarter. The average grade of the ore was 1.56 per cent copper.

Of still more interest from the point of low cost of production of copper is the report of the Nevada Consolidated Copper Company for the fourth quarter of 1910. The output of copper for that quarter was but 15,698,595 lb., a decrease of about 15 per cent compared with the preceding quarter. The ore treated averaged 2 per cent copper, and the cost per pound of metal produced, after writing off depreciation on the Steptoe plant, is 6.7 cents. The total earnings of the company for the quarter were $1,046,527.

The Goldfield Consolidated Mines Company's annual report for the fiscal year ending Oct. 31, 1910, contains some interesting facts bearing on gold recovery. The mill ore treated amounted to 265,351 tons, of an average value of $36.99. The highest grade of mill ore was treated in April, 1910, when the value was $51.06, and the lowest in February, 1910, the value being $30.86. The average percentage extraction for the year was 93.98; the highest percentage was 95.78 in April and the lowest was 92.41 per cent in October, 1910.

Comparison with last year's report will show that there has been no decrease in operating costs coincident with increased tonnage at the 100-stamp mill. This is accounted for wholly by increased cyanide consumption, caused by the constantly diminishing proportion of oxidized ores and increase of sulphides from the lower levels. Leaving this factor out of consideration the plant has worked exceedingly well. In crushing efficiency, cost of operation and recovery of gold it has fully met expectations.

The capacity of the 100-stamp mill was increased during the year by the addition of six 6-ft. Trent Chilean mills and 24 No. 3 Deister slime tables. The installation has increased capacity from 650 tons to 850 tons per day and has been highly successful. If the cost for chemicals were the same this year as last the report of operations would show a reduction of 35 cents per ton for this year as compared with last. A new refinery is being built, located at some distance from the plant. It is of reinforced concrete construction and will cost about $25,000. It will effect a saving of $5,000 per month. A new and complete fire protection system has been installed since the fire last year. This cost approximately $50,000, but will prevent the recurrence of such accidents as that of last year, which cost the company $156,446.

The First Cyanamide Process Installation.

It is rather complimentary to the soundness of the principles of the Clancy cyanide process that within a few months after they were publicly announced a Colorado company decided to erect a mill embodying them. The Ajax Gold Mining Company, with mines at Victor, Cripple Creek mining district, Colorado, is erecting a 100-ton unit for the treatment of raw sulpho-tellurides by the Clancy process. The ore will be crushed dry, ground in tube mill with cyanide solution, agitated in tanks with the addition of potassium iodide and the application of the electric current; then, with the addition of calcium cyanamide, the solution will be regenerated in the same agitation tanks. The pulp will be filtered by the Moore system and the solution returned for further use.

Preliminary experiments in a laboratory way have thrown more light on the details of commercial operation. For one thing, it has been found that no such current densities as first proposed will be necessary for either extraction or regeneration. The extraction occurs with currents as low as 2 amp to 3 amp, and some experiments have indicated that still lower currents will produce the result desired. The regeneration of the solution also has been accomplished with similar currents and the same solution used for eight to ten weeks has shown little loss of strength. The proper substance to be used as anode is one that has not been settled, although the choice probably rests between fused ferric oxide and Acheson graphite.

Construction of the plant is now under way and the first operation should take place early in the coming summer. The result will be watched for eagerly, as its success will mean much to the Western field. Present laboratory indications are very favorable for success in the commercial application.

The Government-Anaconda Smoke Suit.

If reports are to be credited, and they seem reliable, the federal government is to withdraw its suit against the Anaconda Copper Mining Company in which the plaintiff sought to compel the smelting company to abate the smoke nuisance at Anaconda, Mont. By such an action the government will be credited with acting sensibly in a suit which, in the opinion of many conversant with the facts and conditions, never could have been brought to a successful issue. Personal inspection on the part of government officials has evidently shown them that the Anaconda company has at all times acted fairly and that it proceeded wisely in the first instance by selecting a good place for the erection of the smelter and by making every reasonable provision for getting rid of fume and smoke to the best advantage of all concerned. A change of heart sometimes can be produced by getting the opponent's viewpoint and this seems to have been accomplished in the present instance.

Utah.

The milling interests of some sections of Utah are exercised over the recent introduction into the State Legislature of a bill making it a misdemeanor to discharge mill tailings into a stream. The bill is in the interests of fish preservation, but the mill operators see in it a sure means of closing their plants if it should carry. Inasmuch as but few streams of the State are polluted by mill tailings, and many others are left untouched, it is probable that a compromise can be effected and the matter settled without resort to legislation. The spirit of live and let live, and the greatest good for the greatest number, must prevail if all industries are to thrive.

The Iron and Steel Market,

Bookings of orders for finished steel products during February averaged between 60 per cent and 70 per cent of the total available capacity, being in excess of capacity in wire products, heavy in pipe, less heavy in bars, tin plates and sheets, and relatively light in plates, structural shapes and rails. During January there was a large improvement in the rate of booking and the rate of the closing days of January was maintained through February without important change.

Production has increased steadily through February on account of the increased rate of booking. At the close of the month the steel industry as a whole is running at between 65 per cent and 70 per cent of full capacity, against a trifle less than 50 per cent in the closing week of December.

The increased rate of buying of finished products is due chiefly to the fact that on account of uncertainties as to price and the desire to withhold business until after the annual inventory a considerable volume of business backed up and began to be released after the middle of January. There does not seem to have been any particular change in fundamental conditions, and an improvement in general business is therefore expected to effect an increase in orders from the rate prevailing in February.

The United States Steel Corporation on Feb. 10 announced its "unfilled orders" at the clase of business Jan. 31 at 3,110,919 tons. This represented a gain of 436,162 tons during January, the first gain for a year. The total loss during 1910 was no less than 3,252,274 tons, the high point in unfilled orders since 1907 having been the 5,927,031 tons reported for Dec. 31, 1909. The capacity of the steel corporation, in terms of the products it sells, is commonly taken at about 1,200,000 tons monthly, of

which the January gain of 436,162 tons is 36 per cent, and its shipments in January may be estimated roughly at 40 per cent of capacity, with bookings at 75 per cent. The corporation's January bookings were particularly heavy by reason of the formal entering of a number of rail orders, which had practically been placed some time before. February has not witnessed such heavy booking of rail orders, and while in most products the month's bookings exceed those of January, the grand total may perhaps be found not as large.

The trend of finished steel prices has been upward, although not markedly so, the condition being important chiefly because it presents so strong a contrast to that supposed to exist in December, when there was no expectation of price changes, except in the downward direction. The wire advance of Jan. 23 and the tin-plate advance of Feb. 4 have served to show that finished steel prices can advance and while there is no general advancing tendency it has become patent that the price level is well held and that upon occasion advances can be effected.

The price of tin plates was advanced 10 cents per base box at a conference of producers held in Pittsburgh Feb. 3, the advance becoming effective at the opening of business Feb. 4. The new price basis is $3.70 per base box for 100-lb. coke plates, with corresponding advances for ordinary ternes and heavy-coated ternes and bright plates. The advance was made solely to cover the increased cost of manufacture due to the advance in pig tin effected by the foreign syndicate. There is no means of forecasting the future of the pig tin market, but it may be taken as settled that should the price advance to 48 cents or 50 cents a further advance of 10 cents or 15 cents per box would be made in tin plate. When the former price of $3.60 was established on tin plate, Nov. 12, 1909, pig tin was 30.50 cents and sheet bars $28.50. When the advance to $3.70 was made, Feb. 3, 1910, pig tin was 41.40 cents and sheet bars $24.

All the prospects of the iron and steel industry are distinctly favorable. There has been improvement since the first of the year, and with occasional backsets improvement is expected through the remainder of this year. The causes of the continued decline in prices and activity in 1910 are readily perceived, first, that the recovery of 1909 was overdone, and, second, that during 1910 general trade conditions became less favorable. In its adjustment the iron trade swung too far and at the beginning of this year was in line for a return to normal.

Pig Iron.

The pig-iron market experienced a substantial, though slight, recovery in February. Prices had reached a level giving very small profits to most furnaces and involving to the Mahoning and Shenango Valley furnaces an actual loss. The fractional gains in February were important as showing a change in the price trend rather than as making a material difference in the general level. The International Harvester Company purchased a total of about 100,000 tons of foundry iron, divided between Northern and Southern, and one or two other Central Western consumers were large buyers. Southern iron stiffened so that concessions from the $11, Birmingham, price on high-phosphorus irons disappeared and on standard Alabama grades the $11 price became applicable only to deliveries this side July 1, later deliveries being held at 50 cents advance. The Buffalo market, after making prices of $13.75, Buffalo, and perhaps lower, for No. 2 X, in competition with eastern Pennsylvania furnaces for New England business, advanced to $14 and higher. Basic iron in eastern Pennsylvania advanced to $14.50, delivered, after some large sales at $14.25, other grades being unchanged in the East. In the Pittsburgh Valley market Bessemer remained at $15, valley; $15.90, Pittsburgh, as it has been since August, there being a number of sales of small tonnages, including one lot of 1000 tons for prompt delivery and another of 1250 tons for delivery 250 tons per month. The foundry-iron market firmed up, all prices at $13.75, furnace, being withdrawn and leaving the market squarely on the basis of $14 at furnace, equal to $14.75 to $14.90, Pittsburgh, depending on location. A few small lots have been sold at $14.25, furnace. Basic iron has furnished by far the most interest. Owing to the disappearance of one merchant furnace seller through the sale of the Midland properties to the Crucible Steel Company one or two other furnace interests marked up their price from $13.25, valley, at which sales were made early in February, to $14, furnace, which during the second half of the month was the lowest price made by furnaces. Meanwhile sales were made at advancing prices by middle interests, the course being pretty steadily that after one or two sales at a given price a slightly higher price would be demanded on the next inquiry. A sale of 10,000 tons was made at $13.50, then sales of 5000 tons or more were made at $13.60, this being followed by a sale of 2000 tons at $13.65 and this in turn by several odd lots at $13.70 and $13.75, leaving the market in the closing days of the month on the basis of $14 asked by furnaces, and last market sales at about $13.75, equivalent to $14.65 to $14.90, Pittsburgh.

Steel.

The market has been very steady at $23 for billets and $24 for sheet bars, f.o.b. Pittsburgh or Youngstown, for either Bessemer or open-hearth, and $29, Pittsburgh, for rods. A decided disinclination to sell open-hearth sheet bars at $24 developed about the middle of the month. One interest, which had sold a special quality of open-hearth bars, suitable for deep stamping, at $24, obtained $25 on a lot of upwards of 2000 tons. Specifications on contracts for billets and sheet bars have improved and one branch of the consuming trade, the tin-plate mills, have been specifying practically their maximum tonnages on regular term contracts.

Finished Steel.

Finished steel prices are firmly held all along the line, as has been the case since early in December, and are as follows, f.o.b. Pittsburgh, except where otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, 1.40 cents for tank quality.

Shapes, 1.40 cents for beams and channels, 3 in. to 15 in., inclusive, zees and angles 2 x 3 and larger.

Steel bars, 1.40 cents, base; iron bars, 1.40 cents, Pittsburgh; 1.30 cents, Chicago.

Wire nails, $1.75, base, per keg; plain wire, 1.55 cents, base; galvanized barb wire, 2.05 cents; painted barb wire, 1.75 cents.

Black sheets, 28 gage, 2.20 cents; galvanized, 3.20 cents; blue annealed, 10 gauge, 1.65 cents; painted corrugated roofing, $1.55; galvanized, $2.75 per square.

Tin plates, $3.60 for 100-lb. cokes.

The Non-Ferrous Metal Market

Since our last report the metal market has been without feature except as to transactions in tin and copper. A fair volume of business continues to be transacted, but the uncertainties of the market confine purchases almost to immediate needs.

Copper.—The Copper Producers' Association report for January was made public on Feb. 8 and showed an increase in surplus. The production and imports for January were 115,676,591 lb. and although this figure showed a decrease of 7,642,628 lb. as compared with December the decrease in exports gave an ultimate surplus on Feb. 1 of 142,439,490 lb., which was an increase of 20,409,295 lb. This increase is not viewed unfavorably by a Western authority, who regards the increase as due to natural causes occurring at or near the end of the year when producers and refiners make a special effort to clean up accumulated stocks. The market has been unsettled and the agencies have effected business at a concession from the asking price. Lake copper is quoted at 12.5

cents to 12.75 cents, and electrolytic at 12.25 cents to 12.30 cents.

Lead.—The market has been quiet and without feature. The American Smelting & Refining Company has maintained a price of 4.50 cents, but other sellers have not reached this figure. New York quotation is 4.45 cents to 4.50 cents and St. Louis, 4.27½ cents to 4.30 cents.

Tin.—Since our last report tin has reached a high figure, selling at about 43 cents, but has dropped again quite as suddenly. The market has been spasmodic owing to the uncertainty of the intentions of those who control the foreign market. The last New York quotations are about 40 cents.

Spelter.—The market has been unsatisfactory, but a fair volume of business is reported and the prospect is for better conditions. The New York market quotes the metal at 5.42½ cents to 5.47½ cents; St. Louis at 5.27½ to 5.32½, which is lower than last month.

CORRESPONDENCE

Efficiencies of Electric Furnaces.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—In the last volume of the *Transactions* of the American Electrochemical Society a statement was published, apparently with deliberation, which, if left unanswered, might seriously mislead those who accept it.

The statement is that the lower the temperature of the outside of furnace walls of different materials the less the heat loss through the walls, hence the higher the efficiency of the insulation of the walls. The thickness of the walls is assumed to be the same, and for the purpose of comparing different materials composing the walls of this given thickness (as proposed by that author) it is assumed, for discussing the present feature, that the nature of the outside covering is the same. In other words, all conditions are the same except the material of the walls, the loss through them and the outside temperature.

It is furthermore stated by that author, by way of explanation, that the higher the external temperature the less the heat gradient from the inside to the outside and, therefore, the less heat is being taken out of the furnace. This evidently contradicts the first statement. The explanation is correct when applied to any one particular furnace—that is, to any one particular wall material; but it would certainly be incorrect to say that, in comparing different materials with each other, a smaller heat gradient necessarily means less loss. The loss is dependent not only on the heat gradient, but also quite as much on the conductivity of the particular material. Hence the outside temperature of the furnace is absolutely no criterion of the losses through walls of different materials, although that author claims very specifically that it is, whatever else he may have meant by his other remarks, which are not very clear.

The total fallacy of this statement and its alleged explanation is best shown by an actual example. Let us take the same small, simple furnace for which the calculation of the loss was given by me on page 15 of your January issue. The interior is 6 in. x 6 in. x 6 in. The wall thickness is 4 in., and for simplicity let us omit the second layer of brick. Let the temperature of the inside be 1500° C. and on the outside of the wall it will then be 175° when the wall is made of silica brick, which is assumed to have a thermal resistivity of 47 thermal ohms in cubic inch units. The loss through the walls will then be 3½ kw, as was there shown.

Now, for testing the truth of the above mentioned statement, let us assume the walls of the same furnace to be made of copper. This, of course, is an exaggerated case, but the results apply exactly the same, only to a less degree, to any other material. The thermal resistivity of copper is about 0.1 in cubic inch units. And let it be assumed that the outside temperature now is half what it was before, hence 88° C. If the statement under discussion were correct the loss should now be considerably less because the heat gradient is much greater.

Calculations, however, made just as before show that the loss now is 1760 kw, or more than 500 times as great.

If the outside were allowed to get to a bright red heat, say to a temperature of 1000° C., nearly to the melting point of copper and therefore very much higher than the 175° for the brick, the loss will be 625 kw, or nearly 200 times as great, instead of being much less.

The above examples show that for either a higher or a lower outside temperature the loss may be enormously greater. By repeating the calculations for a very high resisting material it could similarly be shown that for both higher and somewhat lower outside temperatures the loss is less than in the original brick furnace. Hence the temperature alone can be no criterion whatsoever in such comparisons of different materials.

Hence the statement referred to is certainly incorrect; one would be committing very serious errors by relying on it. Different materials for walls, therefore, cannot be compared in this way, as that author had proposed. A smaller heat gradient is by no means an indication of a smaller flow of heat through the walls of different materials, but only for the same material. Such a statement should not have been left unchallenged at a meeting of the American Electrochemical Society. Too many incorrect statements have already been made concerning problems involving the flow of heat; as a matter of fact, such problems are generally extremely simple, when correctly understood.

Philadelphia, Pa. CARL HERING.

The Cyanamide Process in the Metallurgy of Gold.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—In your January, 1911, issue there appears an abstract of a paper presented before the Electrochemical Society, Dec. 16, 1910, on the "Clancy Process" of ore-treatment. In the paper referred to Mr. Clancy claims as novel the application of calcium cyanamide as a cheap cyanogen agent in the place of the more expensive sodium or potassium cyanide universally employed in the treatment of gold and silver ores by cyanidation.

I beg to take issue with Mr. Clancy as regards his claim to originality to employ calcium cyanamide in ore-treatment in place of the more expensive sodium or potassium cyanide as I can show priority in the application of this idea to the extraction of gold and silver from ores. And while Mr. Clancy may claim some novelty in adapting the use of calcium cyanamide to gold and silver extraction by means of electrolysis instead of the more direct method which I have proposed, viz: its transformation into calcium cyanide in a much more simple manner, by subjecting the cyanamide at a red heat to acetylene, water gas or any hydrocarbon gas rich in carbon. This can be simultaneously effected during the process of manufacturing the calcium cyanamide from calcium carbide.

I cannot understand how Mr. Clancy could possibly have presented calcium cyanamide as a cheap and novel substitute of his own invention in place of the more expensive KCy or Na Cy for use in the cyanide treatment of ores, when I already wrote up its application several years ago, first in: My United States patent 911,254, filed Sept. 4, 1907, and issued Feb. 2, 1909, from which I quote the following:

"My invention relates to the treatment of ores and tailing with ammonia-cyanide solutions, for the purpose of extracting their gold and silver content.

"My invention is applicable, not only to the treatment of ores and tailings containing gold and silver alone, but also to such ores and tailings as contain, in addition to gold and silver, such ammonia-soluble metals as copper, zinc, nickel and cobalt.

"The object of my invention is to effect economy in the process; and, to this end, my invention consists in the treatment of the ores and tailings with a solution of ammonia and alkaline earth-metal cyanide, as I shall now fully describe.

"In the treatment of ordinary gold and silver bearing ores and tailings by the cyanide process a cyanide solvent must be used which is not only stable in dilute solutions, such as 0.05 per cent to 0.50 per cent KCy, but must withstand exposure to the atmosphere as well, without decomposition. It must also not contain impurities, such as sulphide, carbides, etc., which would greatly depress the gold and silver extraction coefficient of the cyanide solvent. The cyanides ordinarily used, therefore, are the potassium and sodium salts, KCy and Na Cy.

"These are highly refined, snow-white and almost chemically pure. In this state they are sent to market for precious metal extraction purposes, and are, necessarily, very costly, from 20 to 25 cents per pound. In recent years, however, there has been great development in the cheap production of alkaline earth-metal cyanides, such as calcium cyanide, Ca $(CN)_2$ and Barium cyanide, Ba $(CN)_2$, by means of the electric furnace, from atmospheric nitrogen.

"I have found that these electric furnace products, even impure as they are, if they contain 80 per cent to 90 per cent of the theoretical quantity of cyanogen $(CN)_2$, are available for and may be adopted and used in ammonia solutions, as gold and silver solvents.

"In carrying out my invention, the crude calcium cyanide or barium cyanide is dissolved in ammonia solution of sufficient strength; the insoluble residue allowed to settle and the clear solution applied in the treatment of gold and silver bearing ores and tailings, not amenable to ordinary cyanide treatment, either on account of excessive cyanide consumption due to cyanicides, or on account of percentage of metals such as copper, nickel, zinc or cobalt, which render inert the gold or silver solvent powers of a dilute cyanide solution (KCy or NaCy) such as is commonly used, and cause an excessive loss of the cyanide.

"A working solution, according to my invention, may be made up as follows: Solution of ammonia, 1 per cent or less to 10 per cent (NH_3). Calcium cyanide or barium cyanide, 0.05 per cent to 1 per cent. If this solution be too alkaline, a salt of ammonia, such as the sulphate, may be added to counteract such excessive alkalinity.

"The treatment of the ores or tailings with this solution is carried out in any of the usual or known manners, as by leaching or agitating them with such solution; and, where the ores or tailings contain, in addition to the gold and silver values, such metals as copper, nickel, zinc or cobalt, all these metals including the gold and silver are simultaneously extracted, and the separation of the gold and silver afterwards effected in any ordinary manner.

"It will be seen that by my improvement a very cheap gold and silver solvent is obtained, which overcomes all the objections and conditions above referred to.

"Having thus described my invention, what I claim as new and desire to secure by letters patent is:

"1. The improvement in treating ores and tailings containing gold and silver, which consists in extracting the precious metals with a solution of ammonia and an alkaline earth-metal cyanide.

"2. The improvement in treating copper, nickel, zinc and cobalt ores and tailings with gold and silver values, which consists in simultaneously extracting all the metals with a solution of ammonia and an alkaline earth-metal cyanide."

Then the following periodicals published articles and abtracts relative to the subject: *Mining and Scientific Press*, May 15, 1909; *Engineering and Mining Journal*, April 17, 1909 (Letter), D. Mosher; *Engineering and Mining Journal*, Feb. 27, 1909, (Letter), S. E. Bretherton; *Pacific Miner*, March, 1910; *Mexican Mining Journal*, August, 1910; *Metallurgical and Chemical Engineering*, May, 1910 (Abstract); *Mineral Industry*, Vol. 18, 1909, page 365 (Abstract).

In the above articles, abstracts and letters, calcium cyanide as a cheap cyanide salt substitute produced from calcium cyanamide as per equation.

$$Ca_2\,CN_2 + C = 2\,Ca\,(CN)_2$$

was several times noted and its use recommended by me as a cheap cyanogen agent for extracting gold and silver from their ores.

I trust I have made clear my position in regard to the "Clancy Process" as relates to the use of cyanamide. The fact that Mr. Clancy employs iodide in conjunction with the cyanamide is of no importance to the intrinsic claim involved of employing cheap cyanamide as a substitute for the expensive cyanides of sodium or potassium.

San Francisco, Cal. D. Mosher.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—After a careful perusal of Mr. Mosher's communication I fail to see any cause for discussion as to "priority" in the use of cyanamide in ore treatment. Nowhere, including his patent specifications, does it appear that he suggests the use of cyanamide per se as a solvent for the precious metals. On the other hand, he simply proposes, as many others before him have done, the use of calcium cyanamide as a starting point in the manufacture of calcium cyanide by heating to a red heat calcium cyanamide with other materials in an electric furnace and the product of this mixture—calcium cyanide—he proposes to apply to the treatment of ores.

The German chemists, Messrs. Frank and Caro, many years ago attempted to produce cyanides by this means, but found that this method did not work out. I am reliably informed by those actively interested in the manufacture of cyanamide that fortunes have been spent to make available the application of cyanamide in a thoroughly practical and economical way and these parties have very generously and frankly conceded that I have solved the problem. It seems to me that it would be more to the point if Mr. Mosher took issue with Frank and Caro for the determination of the question of "priority," for there appears to be little, if any, difference in the result finally accomplished by either of them, for they were apparently working along the same lines and the results quite naturally were the same.

As to the idea of my infringing any rights and prerogatives of Mr. Mosher, it will be apparent to anyone reading Mosher's specification that he does not use cyanamide in the cyanide solution, but proposes to use his electric furnace product, which contains calcium cyanide of about 80 per cent cyanogen content prepared by secondary electric furnace treatment of cyanamide, as already described.

In the Clancy process any amide or amidine compound may be used in conjunction with the cyanide solution, such, for example, as urea, guanidine, etc.

It is somewhat surprising that Mr. Mosher does not also claim priority to an amide or amidine compound in conjunction with the cyanide solution.

I trust that I have made the differentiation clear in regard to the Clancy process, as it relates to the use of cyanamide in the cyanide solution and not the use of the calcium cyanide product prepared from calcium cyanamide by special treatment as described by Mosher.

It is abundantly clear from reading Mr. Mosher's specification that he does not attempt to claim the use of raw cyanamide in the ore treatment process, for the simple reason that he, like many others, was not aware of the fact that cyanamide, amide or amidine compound could be used in conjunction with the cyanide solutions until the publication of my patent specifications and the articles which I have written disclosing the same.

New York City. John Collins Clancy.

A New Process for the Refining of Pig Iron.

By J. B. Nau.

The process to be discussed in this article has for its purpose the preliminary refining of pig iron, more especially of phosphoretic pig iron too high in silicon to be treated directly and economically in the open-hearth furnace.

Other methods with the same purpose in view are in successful operation to-day. Thus, for instance, the so-called duplex process, which, I believe, was first recommended by me in 1890 as the best method to treat the highly siliceous and phosphoretic pig iron of the South. As is well known the duplex process, in principle, consists in submitting the raw liquid pig iron to a blow in the Bessemer converter, whereby the silicon and part of the carbon are eliminated from the iron before the latter is taken to the open-hearth furnace.

Naturally in the Bessemer blow some iron is burnt besides the manganese, but no phosphorus is touched. The resulting metal will, therefore, still contain all its phosphorus and whatever carbon it is deemed necessary to leave unburnt in order to keep the metal fluid enough for subsequent operations. The blown metal being of a uniform and regular composition the process has become quite popular in spite of the loss of iron entailing the blow.

It was principally to avoid this loss of metal, as well as to remove phosphorus instead of carbon in the preliminary operation, that the present method was devised.

Several years ago I obtained a United States patent (786,048, March 28, 1905) on a refining method in which I proposed to submit pig iron, running from the blast furnace, to the refining action of solid pieces of iron ore. This method consists in running the liquid iron through a column of heated ore and let a bath of metal accumulate on the bottom of the apparatus in such a manner that the lower part of the refining ore column is kept immersed in the liquid iron.

The intimate contact between iron and ore at a high temperature will rapidly effect the refining to the desired extent and if the final temperature remains high enough both iron and resulting slag will remain fluid enough to be run easily and without difficulty from the refining apparatus.

The final temperature in the operation will be influenced by: (1) The surplus or available heat stored away in the liquid iron running from the blast furnace. This temperature is mostly several hundred degrees Centigrade higher than necessary for good fluidity and the surplus heat thus carried can be made to largely contribute to the success of the refining operation. (2) The heat brought into or developed by the reaction taking place in the refining. This heat depends on several factors, such as amount of gangue in the refining ore, sensible heat carried by the refining ore, which can easily be heated up to 1000° C. or more without melting.

It also depends on the amount of silicon, phosphorus, etc., present in the original pig iron.

The elimination of silicon by means of Fe_2O_3 will be accompanied by a rise of temperature, while the elimination of phosphorus, and especially carbon, will under the same conditions be accompanied by an absorption of heat and consequently a lowering of temperature.

Hence a pig iron with a higher silicon content will be more satisfactory from a calorific standpoint.

Thus with a good temperature of raw pig iron and refining ore and satisfactory chemical composition of the same a final temperature can be obtained high enough for all practical purposes.

But a metallurgical process cannot be declared successful without its being so under all reasonable conditions. There would certainly occur many instances where the preliminary conditions necessary for success could not be obtained readily and where, therefore, the final temperature could not be kept high enough to have the metal sufficiently fluid.

The special purpose of the present invention is to provide the method patented by me several years ago with means that will make it successful at all times and under all reasonable conditions.

This can be best obtained by carrying out the operation in an electric furnace, especially built to create easy immersion of the refining ore in the metal to be refined.

Outline Description of Electric Furnace.

The furnace used for the process may vary.

In the present instance I have devised an electrical furnace capped by a water-cooled C. I. roof and surmounted by an ore shaft with a lateral inlet for the liquid pig iron to be refined. Vertical electrodes penetrating the roof are placed around the shaft. The bottom is made of carbon paste and the electric current playing between the electrodes and the carbon bottom traverses the liquid metal and slag, thereby keeping it heated up to the desired temperature in case there is not enough heat developed by the reaction.

If the heat conditions are enough no electric current need be turned on. Thus success is made possible under all conditions.

The furnace is so arranged and the operation will be so conducted that the refining ore necessary will always be kept immersed or made to be immersed to any desired depth in the metal to be treated and as soon as the ore in the bath is consumed and has to be replaced by new ore the latter will always be made without any trouble to be immersed in the liquid bath. The means employed for doing this are of the simplest kind and the buoyancy of the liquid metal can never prevent the much lighter ore from sinking down into the heavier liquid metal wherever the special means employed for that purpose are put in operation.

As it will be shown hereafter that on the other hand perfect fluidity of the refined metal and the resulting slag will at all times be maintained through electrical heating the method cannot but be successful.

Balance of Materials in the Elimination of Silicon, Phosphorus and Manganese.

In an article published in the *Iron Age* of March 23 and April 6, 1905, I have established a thermal calculation of the process which, owing to a mistake in the balance of material, I have since found to be not quite correct.

Therefore, in this paper I again establish that calculation and base it on a temperature of 1400° C. for the inflowing liquid iron from the blast furnace and 800° C. for the refining ore and guided by this thermal calculation I figure out how much electrical power I will require to keep the final temperature of the refined metal and the resulting slag at 1400° C.

I also calculate more roughly how much electrical power I will require when availing myself of the heat stored away in the pig iron to be refined to the extent of allowing the temperature of the refined metal to drop from 1400° C. to 1250° C. The calculations follow here in kilograms and Centigrades.

Assumed composition of pig iron to be refined:

	Si	Ph	Mn	C
In percentage	2%	1%	1.5%	3.5%
Per ton	20 kg	10 kg	15 kg	35 kg
Removed in the refining.....	19 kg	8 kg	13 kg	0
Refined metal will contain.....	1 kg	2 kg	2 kg	35 kg
In percentage	0.1%	0.2%	0.2%	3.5%

The refining ore is supposed to contain 90 per cent of Fe_2O_3 (63 per cent Fe) and 10 of gangue supposed to be SiO_2.

Slag to be formed is supposed to be in the nature of a puddle cinder with 50 per cent of metallic iron.

Results obtained in the refining:

19 kg of Si yielding 40.72 kg of SiO_2 will require 21.72 kg O
8 kg of Ph yielding 18.32 kg of P_2O_5 will require 10.32 kg O
12 kg of Mn yielding 16.78 kg of MnO will require 3.78 kg O

40 kg eliminated 75.82 in slag 35.82 kg O

This O being solely derived from the refining ore the amount of the latter must be sufficient

(1) To oxidize the elements Si, P and Mn to the extent indicated,

(2) To obtain a slag containing 50 per cent of metallic iron, corresponding to 64.283 per cent of FeO.

The unknown quantities in our problem are:

The weight of the slag obtained..... $= x$

The weight of the ore used..... $= y$

We know that the ore used contains 10 per cent of SiO_2 and (90 per cent of $Fe_2O_3 = 63$ per cent Fe and 27 per cent O), hence $y = 0.63\ y$ iron $+ 0.27\ y$ O $+ 0.10\ y$ SiO_2.

We also assume that the slag contains 64.283 per cent FeO and 35.714 per cent gangue = 100 per cent, hence $x = 0.25714 \times$ gangue $= 0.64286\ x$ FeO.

The total oxygen required in the refining is 35.82 kg and the weight of the oxidized elements removed is 75.82 kg.

As the gangue of the slag is composed of the gangue derived from the ore and the oxidized elements eliminated from the iron we have equations

(1) $$0.35714\ x = 75.82 + 0.10\ y$$

On the other hand the total oxygen will be derived from the ore, hence equation

(2) $$35.82 + \frac{16}{72} \times 0.64286\ x = 0.27\ y$$

The two equations will finally give us:

$y = 287.6$ kg of ore and

$x = 292.83$ of slag = 104.582 kg gangue and 188.248 Fe O (50 per cent Fe).

The 287.6 kg ore containing 90 per cent = 258.85 kg of Fe_2O_3 with..... 77.652

kg O, of which will be used for purifying..... 35.820

Leaving for FeO in slag..... 41.832

On the other hand, the slag contains 50 per cent = 146.415 Fe, corresponding to $146.415 \times 2/7 = 41.833$ kg O, obtained from 209.164 Fe_2O_3.

This leaves $258.85 - 209.16 = 49.69$ Fe_2O_3, yielding 34.77 kg directly reduced iron.

Composition of resulting slag:

		In %
SiO_2 derived from ore $287.6 \times 0.10 = 28.76$)		
SiO_2 derived from refining $= 40.72$ (	69.48.....	23.72
P_2O_5	18.32 kg	6.26%
MnO	16.78	5.73
FeO	188.25	64.286
		99.996%

The balance sheet of materials will be:

Put in Refiner.		Taken Out of Refiner.	
Pig iron	1000	Refined iron	960
Iron ore	287.6	Slag	292.83
		Iron reduced	34.77
Total	1287.6	Total	1287.60

Thus, under the conditions considered, each 1000 kg of pig iron treated will yield: 994.77 kg of refined iron containing very nearly 0.1 per cent of Si — 0.2 per cent Ph — 0.2 per cent Mn and 3.5 C and 292.83 kg of slag with 50 per cent of Fe.

No addition of flux, such as, for instance, limestone, was considered. The presence of limestone, on one hand, would no doubt reduce the amount of Fe found in the slag and, on the other hand, it might make it of considerably less value than a slag containing 50 per cent of iron and 5.73 per cent MnO.

Heat Balance in the Elimination of Silicon, Phosphorus and Manganese.

Specific heat of ore containing 10 per cent SiO_2 and 90 per cent Fe_2O_3 from 0° C. to 800° C. = ... 0.21

Specific heat of iron from 0° C. to 800° C..... 0.157

Specific heat of slag from 0° C. to 800° C..... 0.21

Total heat carried by slag at 1400 C..... 500 calories

Total heat carried by liquid iron at 1400° C.... 300 calories

Silicon burning to SiO_2 develops..... 7830 "

Phosphorus burning to P_2O_5 develops..... 5760 "

Manganese burning to MnO develops..... 1723 "

Iron burning to Fe_2O_3 develops..... 1796 "

Iron burning to FeO develops..... 1352 "

The heat of formation of slag is not known, but considering that wherever heats of formation of phosphates and silicates were established the heats of formation of phosphates per unit of acid were always found to be much greater than the heats of formation of silicates uniting with the same amount of the same base one, no doubt, will remain far below the truth when taking for the phosphates the same heats of formation per unit of acid as for the corresponding silicates.

It may also be noticed that heat of formation per unit of a silicate of lime of lower basicity is considerably less than the heat of formation of a silicate of higher basicity, hence per analogy one may assume that the heat of formation per unit of acid of a silicate of iron of higher basicity is much higher than the heat of formation of FeO, SiO_2, the only one that to my knowledge was ever established.

Taking, therefore, the same heat of formation for phosphates and silicates and adopting as unit 150 calories obtained when one unit of SiO_2 combines with FeO to form FeO, SiO_2 I undoubtedly will remain far below the truth and therefore remain within very conservative limits.

The heats of formation of silicides, phosphides and carbides are too uncertain or too little known to be considered here. Their dissociation would no doubt be accompanied by an absorption of heat and a lowering of temperature, but it may be fairly assumed that their omission will be counterbalanced by the omission of the source of heat resulting undoubtedly from the higher heat of formation of the slag than the one considered.

The heat lost by radiation was based on the figure of 440,000 calories per ton of iron established by Gruner in his studies of the blast furnace. As Gruner obtained this loss by difference between the total heat supplied and the actual heat absorbed, both in reactions and in the gases leaving the furnace, and as his calculations were based on a run of 24 hours of a blast furnace making less than 40 tons of iron per day—and as his loss includes also the heat carried off by the cooling water—the item of heat loss due to radiation in a refining apparatus of a capacity of 500 tons per day, having no cooling water and with very much less radiating surface than Gruner's blast furnace, may be considered very ample.

The itemized heat balance per ton of iron treated will follow here:

LIQUID IRON AT 1400° C.[1] ORE AT 800° C.

Heat Supplied:	Calories.	
19 kg of Si will give 19×7830.....	148,770	
8 kg of Ph will give 8×5760.....	46,080	
13 kg of Mn will give 13×1723.....	22,399	
59.04 SiO_2 and P_2O_5 will give 59.04×150....	8,854	
SiO_2 from ore is omitted.		226,103
Heat Spent:		
35 kg iron—reduced from $Fe_2O_3 = 35 \times 1796 =$	62,860	
heated from 800° to 1400° = 35		
$(300 - 800 \times 0.157) =$	6,104	
$293 - 40 = 253$ kg of slag		
Heated from 800° to 1400° = 253		
$(500 - 800 \times 0.21)$	83,996	
The 40 kg of constituents removed were at 1400°		
209.16 kg of Fe_2O_3 reduced to FeO		
$209.16 \times 444 =$	92,867	
Heat lost by radiation (per ton).....	25,000	
		270,827
Heat deficiency		—44,724

Balance of Material in the Elimination of Carbon.

All conditions remaining the same the above heat balance might be considered a constant.

So far we have not considered the carbon, whose elimination will largely depend on the temperature and the length of contact. Still the elimination of a small percentage only of carbon as CO will constitute a great disturbing factor in the heat balance and it is, therefore, necessary to consider its elimination within the limits that it can reasonably be expected to take place.

We apply the calculations to the elimination of 1 kg of C. We shall have again:

Ore necessary: $y = 0.63\ y$ iron $+ 0.27\ y$ O $+ 0.10\ y$ SiO_2

Slag: $x = 0.35714\ x$ gangue $+ 0.64286\ x$ FeO

With the removal of carbon the weight of the slag is increased only by a corresponding amount of gangue and FeO (50 per cent Fe) derived from the ore.

Hence in this case we have

(1) $0.35714\ x = 0.10\ y$

The total oxygen entering into the reactions will be composed of 4/3 kg necessary to remove C as CO plus the oxygen of the FeO of the slag. Hence,

(2) $4/3 + 16/72 \times 0.64286\ x = 0.27\ y$

which equation will give us

Slag $x = 1.623$ kg with 0.579 gangue and 1.044 FeO with	0.232	O
Ore $y = 5.7964$ kg with 0.579 gangue and		
5.218 kg of Fe_2O_3 having 3.6526 iron and..	1.5654	O
Oxygen necessary to remove 1 C.....	1.3333	
Leaving O in Fe_2O_3 of slag.....	0.2321	

Metallic iron reduced: $3.6525 - 0.812 = 2.8406$ kg.

In regard to 1 kg of C the balance sheet of materials will therefore be:

Put in Refiner.		Taken Out.	
Ore = ...	5.796	Metallic iron reduced.	2.8406
Carbon = ...	1.000	Slag	1.623
		CO escaping	2.333
Total	6.796	Total	6.796

COMPOSITION OF SLAG DUE TO THE ELIMINATION OF 1 KG OF C.

	In %	
SiO_2 = ...0.579.....	35.68	
FeO = ...1.044.....	64.32	(50% Fe)
Total .....1.623 kg	100%	

HEAT BALANCE DUE TO THE ELIMINATION OF 1 KG OF CARBON.

Heat Giving Factors:	Calories.	
1 kg of C burning to CO.....	2403	
5.79 kg ore at $800° - 5.79 \times 800 \times 0.21 =$	972	
1 kg of carbon at 1400° C. = ...	300	
0.579 of SiO_2 uniting with FeO, 150 calories = ..	87	
Total		+ 3762
Heat Consumed:		
2.84 of Fe reduced from $Fe_2O_3 = 2.84 \times 1796 =$	5100	
2.84 of Fe heated from 800° to 1400° and melted $= 2.84\ (300 - 800 \times 0.17) =$	465	
1.16 of Fe_2O_3 reduced to FeO $= 1.16 \times 444 =$ ..	515	
1.623 of slag heated from 800° to 1400° C. = 1.623 $(500 - 800 \times 0.21) =$	538	
Heat carried off by 2.333 kg of CO at 500° = $\frac{(2.333}{1.25} = 1.8664$ m.³) $\times (0.303 + 0.0027 \times 5) \times 500 =$	294	
		− 6925
Deficiency of heat per kg of carbon eliminated =		− 3163

Considering that the whole operation necessary to treat one ton of iron will not last more than 10 minutes, which is actually more than there is necessary in the wash process where hardly any carbon at all is removed, at a higher temperature of refining ore we suppose the carbon reduced from 3.50 per cent to 3.30 per cent corresponding to a total of 2 kg of carbon per ton of iron, the loss of heat due to this cause will be:

$$2 \times 3163 = 6326 \text{ calories}$$

Thus per ton of iron treated the whole loss of heat will be:

	Calories.
Removal of silicon, phosphorus, manganese to the extent shown	44,724
Elimination of 2 kg of carbon.....	6,326
Total loss of heat per ton of metal treated.....	51,050

Electrical Power Necessary.

We propose to supply the above deficiency of heat by electrical power so as to keep the temperature of the refined metal and the resulting slag at 1400° C.

If we apply the method to the refining of all the iron made in 24 hours in a 500-ton furnace we will have to refine per hour $500 \div 24 = 21$ tons and we will have to supply $21 \times 51{,}050 = 1{,}072{,}050$ calories per hour.

Taking the efficiency of an electric furnace as 80 per cent the current would have to supply

$$\frac{1{,}072{,}050}{0.80} = 1{,}340{,}062 \text{ calories}$$

corresponding to

$$\frac{1{,}340{,}062}{640} = 2091, \text{ say, } 2100 \text{ electric hp-hours.}$$

This electrical horse-power would be enough to refine the iron as fast as the furnace can make it.

The calculations are based on heat factors as they are known to-day and on that basis the results obtained should be correct.

Still, some of them are to a certain extent doubtful and their use may influence the results and show the heat conditions to be different from what they might be found in practice.

There will be no harm if practice shows a smaller heat deficiency than the one established; but, on the other hand, the heat deficiency might be found larger.

When it is considered, however, that the final temperature of 1400° C. is far above the temperature that perfectly fluid metal requires to easily run from the refining furnace, we have at our disposal a factor of safety of great value of which we have made no use. The temperature of the metal and cinder in a puddling furnace reaches hardly if ever 1250°. The temperature of pig iron running from the cupola seldom reaches 1250° C. and is mostly below 1200°. Yet at these temperatures both puddle-cinder and cupola metal are very hot and very fluid.

It would therefore appear to be unnecessary to have a final temperature of 1400°. If we allow this temperature to drop to 1250° excellent results are assured and the refining operation will become far more economical in so far that now we actually make use of the surplus heat unnecessarily stored away in the liquid iron and a correspondingly large amount of heat to be supplied by electricity will be saved. A cursory examination of the problem made under this new aspect will give the following results:

Allowing the temperature to drop from 1400° C. to 1250° C. would liberate an amount of heat as shown below:

1000 kg of iron from 1400 to 1250 liberates $1000 \times 150 \times 0.23 =$	34,500 C
293 kg of slag liberates $293 \times 150 \times 0.30 =$	13,185 C
Total loss	47,685 C

Leaving out all other factors that would make the case appear under a still more favorable light the amount of heat to be furnished by electricity will now be reduced to $51{,}050 - 47{,}685 = 3365$ calories per ton, or per hour $3365 \times 21 = 70{,}665$ calo-

ries, requiring a horse-power of $\frac{70,665}{0.8 \times 640} = 138$ hp.

Since, roughly speaking, the 47,685 calories correspond to 150° C., 51,050 calories would correspond to about 160°, which means that no electricity would be required when allowing the temperature to drop to 1240°, high temperature of very fluid metal running from the cupola.

Thus at times when conditions are quite favorable no electricity need be applied for success; but with less favorable conditions some electricity would be necessary.

Probably at no time the full amount of 2100 hp will be required, but with the electrical power at hand always ready to be applied success is assured under all conditions.

It might further be stated that the size of the hearth or crucible of the furnace can be determined so as to keep the metal to be refined and the refining ore in contact for any reasonable length of time, thereby making it possible to extend the heating of the metal over a greater length of time, which naturally would afford every facility to again sufficiently raise the temperature of the outflowing metal should this latter have cooled down more than desirable.

New York City.

Some Electric Furnace Notes.

By Joh Härdén, E. E.

The valuable contributions to the knowledge of the proper dimensions of furnace electrodes made by C. Hering in several issues of this paper will no doubt be greeted by furnace designers with acclamation. Many were the difficulties confronting the designer in the earlier days of the electric furnace era, both regarding the best size of electrodes and the most efficient way of arranging them, and also, last but not least, where to get them.

Some twelve years ago the author was given the problem of designing a graphitizing furnace for carbon rods in Russia.

The current available was direct current, about 3000 amps by 65 volts, no alternating current being obtainable at the works; in fact, the furnace was to be operated in series with a row of electrolytic cells and intended to absorb surplus power in a useful way. The carbon rods to be graphitized were about 3½ in. diameter by 4 ft. long. Owing to these two facts the operation could not be carried out "in bulk" as is the practice at Niagara, but had to be in a continuous operation. It was found subsequently that the best method under the circumstances was to pass three rods at a time slowly through the furnace, followed by three others in succession.

At first, attempts were made to produce a large arc in a carbonaceous atmosphere. This method had, for obvious reasons, to be abandoned very soon. The arc behaved very well for 6 to 8 hours, but as soon as the interior of the furnace got well heated the furnace walls became part of its path being conductive at that temperature, and even directing magnets had no beneficial influence owing to the irregular paths taken by the arc. Also, the rods to be treated got scorched and injured by the action of the arc.

In this connection it might be mentioned that the suggestion made by A. Mahlke in Vol. IX, No. 1, p. 42, to broaden the active ends of the electrodes, so as to obtain a better distribution of the arcs and the heat in the furnace, is not likely to be successful. Anyone who has had an opportunity to observe the arc, even in a furnace of the largest size, will have noticed how the base of the arc is always concentrated to a comparatively small area, wandering about on the surface of the electrode, how large this also may be in cross section. This is no doubt due to the fact that the arc requires carbon vapor of high temperature (or any other ionized medium of high temperature), and as this cannot take place at the same instant over the whole surface of the electrode, the arc will always be concentrated at its base. The same may also be observed in a Mercury-vapor lamp; the arc forms only a comparatively small spot on the surface of the mercury cathode.

Reverting again to the graphitizing furnace a further attempt was made to convert it into a resistance furnace in the following way: Two electrodes, about 6½ in. square, were placed inclined on opposite sides into the furnace chamber of fire brick; the bottom consisted of electrode stumps and stamped coke. The furnace was partly filled with granular charcoal, in which the electrodes were embedded about 7 in. to 8 in.; due provision was taken to prevent the current passing through the furnace walls, similar to the arrangement used in the pig iron smelting furnace by Gronwall & Stalhane.

This arrangement would work satisfactorily for about a day or so; after that period, the trouble began. In spite of the air being excluded as far as possible from the electrode collars the electrodes were worn out just inside the furnace room very rapidly, while the active ends grew in thickness by the setting-on of carbonaceous matter to such an extent that the electrode took the shape of an irregular mushroom, causing great difficulties in the regulating.

A final alteration was then made, which proved successful. The bottom of the furnace was built up on a hollow cast-iron plate, similar to that in a carbide furnace, two of which were in operation at the works as well. Electrode stumps, about 8 in. high, were placed in carbon cement on the iron plate and the brickwork erected to form the furnace chamber.

This bottom plate formed the positive electrode, while the negative one consisted of a 6½-in. x 6½-in. carbon suspended from above, by means of a water cooled holder, through an opening in the furnace roof. The furnace chamber was filled with granular charcoal as before, in such a manner as to reach the upper electrode and sloping down at the sides, which prevented the current passing through the walls. The rods to be graphitized were passed three by three slowly through the glowing mass of charcoal and allowed to cool in coal dust on a gantry. The rods were examined as to degree of graphitizing by tapping with a steel bar; the sound emitted gave a good idea of the process; also the polishing effect by rubbing.

One difficulty remained to be solved; the roof was soon destroyed in each case, and we may assume that this difficulty is still a great stumbling block, even to-day, in all electrode furnaces. In the above instance, the problem was solved in this way: The roof of the furnace was arched in by means of scrapped or curved carbon electrodes, separated and wedged in by means of intermediate wedge-shaped high-grade fire bricks, to prevent leakage of current. After some adjustment this kind of roof could be made to last for 8 to 9 months in spite of the continuous run day and night at a tremendous temperature, and despite the fact that the furnace was emptied and fresh charcoal refilled every twenty-four hours, which caused a heavy fall in temperature in fact, this refilling was the primary cause of the rapid breakdown of the original brick roof. One top electrode would, under these circumstances, last four to five days, its dimensions being, as already stated, 6½ in. x 6½ in. x 4 ft. 6 in., and the current 3000 amps to 3500 amps at 40 volts to 45 volts. As far as is known to the author the bottom needed no repair at all during a campaign of four years.

A curious incident in the case of the trials with the arc-design was the upshot of a number of further experiments and also some patents.

When the large arc was started, violent rushes of current took place, the whole furnace being cool. This was strongly objected to by the power station master, as it caused very strong surging between the large engines running parallel; the regulating device of the steam engines was of such nature as to be particularly sensitive in this respect.

While awaiting the construction of a suitable starting resistance (an iron band immersed in running water) a makeshift was made in trying to start the arc, and also to prevent

its extinguishing, by means of a spark coil, made to discharge between the electrodes. In order to prevent the spark taking any other way than was intended, a condenser was connected to the sparking circuit and a primitive reaction in the power circuit.

By this means it was quite possible to start the arc without any serious current rush and the tendency of the arc to go out before the furnace was heated ceased if the spark was kept going.

This device was first tested with a smaller arc and narrower electrodes; it was then observed that the tips of the electrodes got more quickly graphitized and that the graphite formed was of a more flaky appearance when the spark had been in operation for some time, though not always, only under certain conditions. The whole phenomenon was at first thought to be accidental only, but on further investigation it was found that the graphitizing could, under favorable conditions, be somewhat accelerated by introducing condenser discharges of practical magnitude. A specially made spark coil and a suitable condenser were therefore installed and put into permanent use; the workmen were protected from the discharge by means of heavy mica collars, surrounding the auxiliary electrodes through which the discharges were introduced into the furnaces.

Other and more pressing work prevented a more systematic and exhaustive investigation as to the economical efficiency of the method; it may be said in this respect, however, that its use appeared to be justified. The workers, a man and a boy per shift, were paid after piecework for a minimum number of rods, passed by the foreman after each shift, and an additional bonus for each extra rod passed. It was regularly found that if the spark coil had been out of operation for some

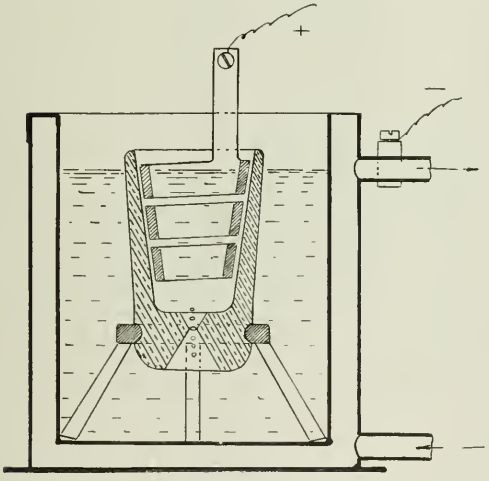

FIG. 1.—INTERRUPTER DESIGN.

time during a shift the number of rods passing examination decreased and the rejected rods had to be sent through the furnace again; therefore the workmen showed a keen interest in keeping the coil in going order.

As there was no alternating current available at the works, the coil had perforce to be operated by direct current, 125 volts. Anyone who has had the task of keeping a large coil, giving a 12-in. to 14-in. spark of great volume, going day and night without breakdown for several months at a time will testify that the finding of a suitable interrupter is by no means an easy problem.

At first, the ordinary mercury make and break, consisting of two motor-driven vertical pins, was tried, but it was soon found that this did not answer. The pins were rapidly worn out, regardless of what metal they were made; besides, the mercury soon got clogged up in spite of a thick strata of oil over it. Carbon rods lasted longer, but the spark was greatly diminished, owing to insufficient rapidity of break.

A turbo-interrupter was then tried, in which a mercury jet in the well-known manner was projected against a toothed iron wheel, moving in oil or cooling liquid. Even this proved futile, as the teeth of the wheel were soon worn off by the sparking; the mercury got so clogged in three or four days that it had to be replaced. To prevent this latter nuisance, a jet of coal-gas was introduced into the vessel, so as to prevent oxidation, but even this measure, though it did some

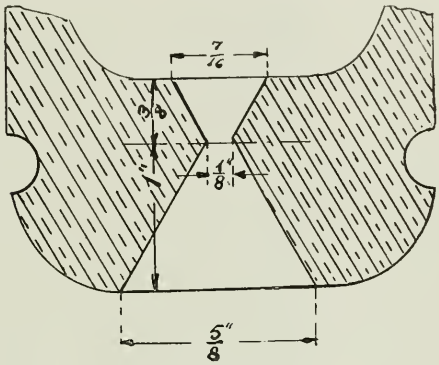

FIG. 2.—CORRECT SHAPE OF BORING.

good, did not secure from breakdowns to the extent of commercial efficiency.

The electrolytic interrupter was finally resorted to and, in spite of its low electric efficiency, proved to be more satisfactory than the others. A platinum point, as introduced by Dr. Wehnelt, was first tried, but was soon destroyed by the current. After a good deal of experimenting it was found to answer the purpose best if a large porcelain insulator drilled through the top, without any metal point at all, was used.

As indicated in Figue 1, the insulator was suspended in a doubled-walled vessel of lead, cooled by running water. A lead spiral formed the inner, or positive electrode; the active liquid was sulphuric acid of about 1.14 Sp.W. The paper condenser in the base of the coil was not in circuit while this interrupter was at work.

With this device it was found quite possible to keep the coil going day and night for many months, only stopping about every fifth day for cleaning and replacing of the acid, which was gradually vaporized; but such stoppage only required about 15 to 20 minutes.

The hole drilled in the insulator was gradually widened by the action of the current. It had to be replaced about every three months, for which purpose a spare one was always kept.

At the beginning, some difficulty was found in the tendency of the apparatus to act as a pump. In some cases the acid was driven out through the bottom hole into the outer vessel, causing the working to be irregular and producing much heat. Again, with another insulator substituted, the acid rose in the inner room so as to overflow and cause short circuit.

It was soon found that the shape of the hole was responsible for this behavior. If the hole sloped too much upwards, the gas bubble causing the interruption exploded *upwards*, thus driving the pile of liquid up into the inner vessel, causing a surging from underneath, so that the liquid in the outer vessel rushed inwards. If this happened rhythmically, as was often the case, the insulator was soon filled to overflowing.

On the contrary, if the boring widened too acutely *downwards* the bubbles burst outwards and drove the liquid into the outer vessel.

In Fig. 2 is indicated the correct shape of the boring, with which no surging took place. The hole should be well polished, or preferably glazed, when the action was much minimized. The period of interruption was adjusted by means of a variable inductance in the primary circuit, so as to give the best effect.

Large glass condensers were used in the secondary circuit to produce the oscillations necessary.

With this arrangement the breakdowns were very rare, and the whole apparatus could be left for four to five days without inspection.

London, England.

Metallurgical Engineering Education.

By Victor C. Alderson.

The forces which influence the course of study in our technical schools are different from those which influence the cultural college. In the case of the latter these influences are from within. The members of the faculty offer such courses as they deem wise, treat them as they choose, and develop such a man as seems good to them. The graduate goes out trained for nothing in particular; if he succeeds in business, for example, his success is due rather to his natural aptitude for business than to any special training the college of general culture has given him.

In the case of the technical school the influences which determine the training a man shall receive come from without. He enters a profession and must understand its fundamental principles and must start at the bottom. The standard for graduation—the level he must attain—is determined by the profession he intends to enter.

For this reason, the work of our technical schools is more exacting than is the work of the cultural college. In the one case the standard to be reached is determined within the college circle and is more or less indefinite; in the other case, it is fixed by an outside, independent authority and is rigidly determined by the demands of the profession. Naturally, then, in our technical schools there is an exceptionally fine spirit for work, for close application to details, for a close co-ordination of laboratory and lecture room work, for clean-cut, usable knowledge, and for thorough training.

Not many years ago the mining school that offered a course in the general principles of underground work, of timbering, and of shaft sinking, with some little chemistry, and a superficial knowledge of geology, met the needs of students who desired to become mining engineers, and satisfied the demands of the mining industry. Within the last few years, however, the demands of the industry have become so broad and so deep that the older course satisfies neither the needs of the prospective mining engineer nor the demands of the profession.

Mining is now subdivided into coal mining, mining geology, non-metallic mining, metal mining, and metallurgy. The mining school of to-day which would be up to date must recognize all of these branches of mining. It must not make the mistake of allowing its graduates to be such one-sided specialists that, on leaving college, they can do only one thing. The function of the technical school is not to graduate unfledged specialists, but to develop a young man so that he can enter the profession at the bottom and eventually become a man of power and of resources. To this end a thorough grounding in fundamentals is absolutely necessary.

Long observation of men, trained and untrained, leads one to see that the mere practical man soon reaches the limit of his development. This is due primarily to the fact that his observations are limited, he cannot assimilate the condensed experience of others, and he lacks fundamental concepts and general laws. He is filled merely with facts and personal experiences. The trained man, however, has the basal laws of physics, of chemistry, and of mathematics thoroughly implanted in him as a mental substructure into which all future facts and personal experience can be logically placed. In the one case there is, almost universally, a limit of development beyond which a man cannot go; in the other case, there need be no limit to growth and development. If this were not so, our technical schools would have no good reason for existence.

The mining school of to-day must not only feel the pulse of the mining industry but must recognize early the range of pulsation. It is not sufficient to be satisfied with the accomplishments of a decade ago. Coal mining, for example, has become a settled industry. The rewards are not great but they are fairly sure. The most recent demands in this branch of mining are for a thorough knowledge of the action of mine gases, the explosibility of coal dust, rescue work, and "first aid to the injured." A school giving a course in coal mining to-day would be sadly derelict in its duty if it did not include these subjects in its curriculum. The ideals for this work have risen steadily in the past decade.

The mining of the non-metallic minerals has been developing so rapidly of recent years that this branch of mining is even now demanding attention. The clays, shales, granites, lava stones, and marble are now being sought as never before. The cement industry is growing prodigiously and the uses of cement are becoming so numerous that only a specialist can become familiar with them.

Mining geology, also, has only recently come into its own. Herein lies the union of the mining engineer and the geologist. The old time prospector, with his burro, his outfit, and his "nose for ore," is gone forever. In his place is the trained mining geologist whose prospecting is done quite as much underground as on the surface, who understands the principles of ore deposition and the play of dynamic forces, and who can read earth changes with little to guide him. The mining industry needs this man and the schools should supply the material from which he can be developed.

But after all is said the field of ore dressing and metallurgy contains the great problems for the mining engineer. When coal has reached the surface it is ready for market, but when the metal miner brings his ore to the surface his troubles have only begun. If his ore can be shipped directly to the smeltery he is merely relieved of the burden; he passes the problem on to the metallurgist. If his ore must be concentrated, or subjected to some form of local treatment like cyanidation, a new field of work opens before him. In this realm of ore treatment lie the serious problems of the future. Herein lies the great work of the mining schools—the work of training the future mill-man and the metallurgist.

The industry does not need a man versed merely in the theory of inorganic chemistry; there are many such who are not metallurgists. Certainly the metallurgist must be a master of applied inorganic chemistry, but he must be much more. Instead of thinking in grams he must think in tons; he must know not merely the refinements of the laboratory, but also the difficulties to be met in commercial practice. The steady decline in the cost of smelting during the past half century is a silent, though potent, witness to the improvements made. These have not been made by the practical man but by the trained man. There are many problems yet to be solved; it is the duty of the schools to develop the men who can solve these problems. Herein lies the ideal for the mining school. It is well known that neither the practical man working alone nor the theorist working alone can solve these problems. The man who has just the right combination is the ideal man.

The problem, then, before the schools is to make that combination of theory and practice which will develop the man to conquer the problems of ore treatment. Theoretical instruction combined with the ordinary laboratory is the combination generally used. The efficacy of this plan is doubtful. Some-

thing new is demanded in this age. That something is laboratory work on a full commercial scale, so that both the refinements of the laboratory and the difficulties of standard size work may be met and appreciated.

At the Colorado School of Mines this ideal is being realized by the erection and equipment of an experimental ore dressing and metallurgical plant, in which the equipment will all be of standard size and where ore in carload lots can be treated. In planning the building, the idea of flexibility has been kept constantly in mind so that any line of experimental work can be undertaken. The different sections cover ore dressing, cyanidation, roasting, and a section for metallurgical work. The plant will serve various purposes—a laboratory for the students; a place of research for advanced students, for members of the faculty, and for the mining engineer; and an experimental plant for the use of the mining industry.

The ideas involved in the plan are high but no higher than the needs of the industry demand. Since the great problems of the industry lie in the treatment of the ore, it is proper that the means adopted should include a great experimental plant for ore treatment. Such a plant will also provide adequate means for training the future metallurgist so that the school will be doing its duty not only to the mining industry but also to the young men who are looking forward to becoming the metallurgical engineers of the future.

Colorado School of Mines.

The Manufacture of Standard and Alkali-Resisting Portland Cement In Colorado.

Editorial Correspondence.

The statistics of the United States Geological Survey show that the production of Portland cement in the United States made a new high record in 1910, notwithstanding the fact that prices were not satisfactory, particularly in the East. In 1900 the manufacture of Portland cement in the United States

FIG. 1.—NIOBRARA LIMESTONE BED AT PORTLAND, COLO.

amounted to 8,482,020 bbl. The production increased steadily and rapidly until, in 1909, the output was 63,508,471 bbl. This output was further increased in 1910 about 15 per cent to 20 per cent, and is estimated at 73,500,000 bbl. to 75,000,000 bbl.

Portland cement manufacture in Colorado began about twelve or thirteen years ago, and there was but one plant in operation until 1908, when a second was started. In 1909 the third commenced production of a special alkali-proof cement, and the prospects are that all three will be operated at capacity this year. The raw materials used for standard Portland cement in this State are a fairly pure limestone from the Niobrara formation (Fig. 1) and an overlying argillaceous cement rock locally called shale (Fig. 2), and so designated in these notes. These materials are exposed on either side of the Arkansas River between Pueblo and Cañon City, and two of the Colorado plants, those of the Colorado Portland Cement Company and the United States Portland Cement Company, are located on the Arkansas River in Fremont County, at Portland and Concrete respectively.

The Portland Plant.

The Colorado Portland Cement Company operates a 3000-bbl. plant at Portland, Col., employing about 240 men under the direction of Mr. F. W. Brown, superintendent, and Mr. L. E. Foster, chemist. This plant is the oldest in the State. The accompanying illustrations show the lime and shale beds from which the raw materials are taken. Between the strata of limestone occur very thin seams of clay, which, in quarrying, break free from the limestone. It is, however, mixed with the spalled lime rock and sometimes used as part of the raw mixture.

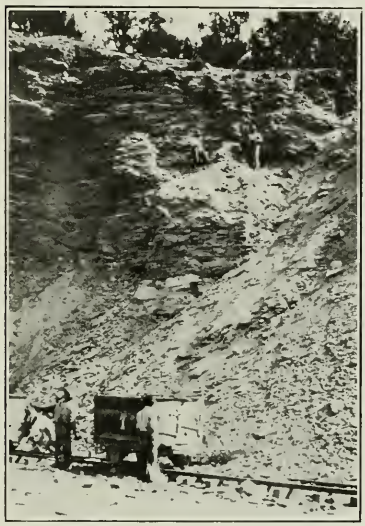

FIG. 2.—SHALE BANK AT PORTLAND, COLO.

Electric haulage is used for transportation to the stock house, where separate large bins are provided for lime rock, shale and spalls. These are drawn off through gates as needed and hauled to the crusher-room, where they are reduced by Gates No. 6 gyratories and rolls to about 1-in. size and elevated to separate bins. From these the crushed materials are properly proportioned and diverted to blending bins located in another building. This series of 20 blending bins is a special feature peculiar to this plant, and provides a means for securing uniformity in the raw mixture, which is drawn from several bins at once. Thus any error which might have been made in proportioning the materials in one bin does not materially affect the composition of the raw mixture drawn from several.

The method of proportioning the raw cement mixture is as follows: Beneath the lime and shale bins are weighing hoppers, one for each ingredient. The shale carries about 67-68 per cent $CaCO_3$ and the lime rock about 90 per cent. The shale is nearly a cement mixture, and lime rock is added in suitable proportion to make a mixture containing 74 per cent $CaCO_3$. The two materials are mixed in 8000-lb. lots, equivalent to about 12 bbl. of cement, and may contain from 7200 lb. to 7800 lb. of shale and 800 lb. to 200 lb. lime rock; or other proportions may be used according to the varying composition of the raw materials. A variation of 400 lb. of lime rock makes a change of about 1 per cent $CaCO_3$ in the mixture.

By this system of controlling the mixture the effect of a change in composition can be determined in one to two hours according to running conditions in the plant; if both dryers are running the change will be effective in about an hour.

This practice of mixing the raw materials before comminution differs from that at the other Colorado plant, but it is apparently effective, inasmuch as the mixing continues through the dryers and conveyors. The dryers are coal-fired and are of the direct-heat rotary-blast type, 50 ft. long and 54

in in diameter. The moisture is reduced to about 0.5 per cent.

The dried mixture is elevated to bins above the comminuters for preliminary grinding. A variety of grinding machines have been used at this plant, both on the raw and finishing sides, and there has been good opportunity to compare their work on different materials. For comminuters the preference at this plant favors the Jeffrey for raw mixtures and the Smith for clinker, as fine grinders, the Fuller mill is preferred for raw mixture and the tube mill for clinker. There is little preference between the Fuller and the tube mill for fine grinding of coal.

One Jeffrey and three Smidth mills are in use as raw comminuters. Of their product 85 per cent passes a 20-mesh screen. This material is conveyed to bins above a battery of five Fuller mills and five tubes, all used for finishing the raw mixture. The Fuller mill has a capacity of about 15 bbl. of rock per hour and requires about 75 hp. The tube will grind about 22 bbl., with a power requirement of 125 hp. Colorado pebbles are used in the tubes, the consumption being at the rate of 45 tons per month, or 1 lb. per barrel. Screen tests of the finished raw mixture show 92 per cent through 100 mesh and 82 per cent through 200 mesh.

The kiln-room contains nine rotary kilns, six being 60 ft. and three 120 ft. long. The 60-ft. kilns are 6 ft. in diameter; one of the 120-ft. kilns is 9 ft. in diameter and the other two are 7 ft. at the feed end and 7.5 ft. at the discharge. The raw mixture enters the kiln with about 8 per cent added moisture and is burned at a temperature of about 2800° Fahr. Southern Colorado slack dried and ground to 90-95 per cent through 100-mesh screens is fired under 3-oz. pressure delivered by Sirocco fans. The coal consumption is 135-140 lb. per barrel of cement. The kilns are operated by variable-speed motors and require about 6 hp for the smaller and 35 hp for the larger.

The hot clinker elevated from the kiln-room may be diverted to the stock pile or, if needed immediately, is cooled in a rotary cooler, 6 ft. x 120 ft., operated by a 32-hp motor. Clinker can be withdrawn from the stock pile by conveyor operating in a tunnel between the clinker storage and the finishing end.

The finishing side of this plant parallels the raw side, the direction of flow of the material being reversed after the clinker is burned. On the finishing side three Smidth comminuters and one No. 8 Krupp mill are used for preliminary grinding and eight tubes for finishing. The former grind about 85 per cent through 20-mesh. At this stage the retarder is added to control the setting time of the finished cement. Gypsum is used, and a sufficient quantity added to give about 1.6 per cent SO_3 in the finished product.

The quantity of gypsum added is controlled by a ratchet-and-pawl device which operates a screw conveyor at the bottom of the gypsum bin. There are several pawls of different lengths, any one of which can be thrown into use, and by using a longer or shorter pawl the speed of the screw can be increased or diminished, with proportionate regulation of the quantity of gypsum discharged. The mixed cement and gypsum are elevated, weighed on a Richardson automatic scale, and conveyed by screws to hopper bins above the tube mills. The tubes grind about 94 per cent through a 100-mesh screen and 78-80 per cent through 200-mesh, which is well above the requirements established by engineering societies, viz., not less than 92 per cent through 100-mesh and 75 per cent through 200-mesh.

The chemical and physical tests made are those customary at cement plants. The raw mixture is sampled hourly at the various stages of its comminution, and tested for fineness and percentage of $CaCO_3$. An average day and night sample of the finished raw mixture is similarly tested. The finished cement is sampled hourly, analyzed for sulphur and tested for fineness, setting time, tensile strength and effect of boiling temperature. Carload shipments are controlled with tensile strength tests on 7-day and 28-day briquets. The following figures are representative of the tensile strength of neat and sand (1:3) briquets, as developed in the times specified:

	24h.	7d.	28d.	90d.
Neat	345	735	850	850±
Sand	...	260	25 per cent gain	15 per cent gain

The following analyses are typical at this plant:

	Raw Mix.	Clinker.	Finished Cement
SiO_2	13.6	23.0	22.3
Fe_2O_3	5.8	3.2	3.2
Al_2O_3	5.8	7.5	7.4
CaO	42.3	64.5	64.0
MgO	0.5	1.0	1.0
SO_3	1.6	0.5	1.4
Ignition loss	36.8	0.1	0.1

The fuel used in the kilns carries about 18 per cent ash, and the determination of this factor is the only control exercised over coal purchases.

The company is making extensive improvements in its plant

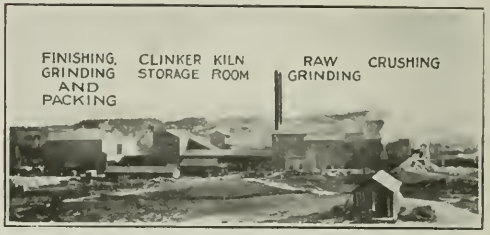

FIG. 3.—PLANT OF THE UNITED STATES PORTLAND CEMENT COMPANY, CONCRETE, COLO.

which will make for more economical operation. New crushing and drying equipment will be installed, and the power plant considerably enlarged, including the installation of a gas-producer plant. The cost of improvements will be $200,000

The Concrete Plant.

About one mile east of Portland is the town of Concrete and the cement plant of the United States Portland Cement Company (Fig. 3). This plant commenced production in 1908, almost a decade after the first operation of the Portland plant, and consequently is more modern in construction and in some features of operation. The plant has a capacity of 1500 bbl. per day and employs about 100 men. Operations are under the direction of Mr. William Fowden, superintendent, and Mr I. J. Dilts, chemist.

The same raw materials are used as at Portland, with the exception that the lime is hand picked and the clay seams and spalls are rejected. The argillaceous material also is carefully selected, only that rich in lime carbonate being used. The clean limestone averages about 91.5 per cent $CaCO_3$ and the clayey cement rock about 71.5 per cent. The plant is so situated with respect to the quarries that the rock is transported by gravity, and the empty cars returned by gasoline locomotive. The successive units of the plant are arranged in a straight line, differing in this respect from the plant at Portland, where the raw and finishing sides are parallel.

The rock is dumped directly to two Symons gyratories, Nos. 5 and 6. These crushers are the same as used in metallurgical plants in the West, a brief reference to which was made in our issue for February, 1911, page 92. The crushed rock is elevated to conical bottom steel bins, three of which are for shale and one for lime rock. These bins hold sufficient material for a 48-hour run of the plant. Each class of material is separately dried and ground before mixing, and in this respect the practice differs from that at Portland, where the raw materials are mixed immediately after crushing and before drying. Belt

conveyers from the bottom of each bin run to two Ruggles-Coles dryers, with exhaust fans and Cyclone dust separators attached.

One of the cardinal points of cement manufacture is the fine grinding and intimate mixing of the raw materials. The tendency at this plant is toward finer grinding, both on raw and finished products. One Williams and two Jeffrey mills are used as raw comminuters, grinding about 88-90 per cent through 20-mesh screen and 45 per cent through 100-mesh. The ground materials are elevated and diverted to bins, of which there are four placed in line, three for shale and one for lime rock. It is from these bins that the raw mixture is made and controlled by a system which is very accurate.

A short screw conveyor draws the material from each bin. The three screws on the shale bins are operated by one variable-speed induction motor, and deliver to a large screw conveyer running at right angles to them. The screw on the lime bin is similarly operated by a variable-speed motor, and likewise delivers to a second screw running at right angles to it. These cross-conveyors deliver to a common point where the lime and shale are mixed. The speed of the motors and screws is controlled by the chemist through rheostats placed in the laboratory. The standard mixture desired is one containing 75.5 per cent $CaCO_3$, and is made up of about 25 per cent lime rock and 75 per cent shale.

By previous experiment the chemist has determined the percentages of lime rock and shale which will be delivered at various speeds of the screws, also the lime carbonate content of the mixture which result from various combinations of speed of both motors. These figures have been tabulated with reference to the position of the pointers on the controlling rheostats, which thus becme an arbitrary index of the mixture being made. The tabulations have been made for a combination of the one lime bin with two shale bins, or with all three shale bins.

Determinations for $CaCO_3$ in the raw mixture are made every 10 minutes, and should the result be much higher or lower than the average desired, the chemist can, by reference to his tables, immediately set his rheostats at a combination which will correct the error. It will be seen that this system exercises a very close control over the composition of the raw mixture, which is another important point in cement manufacture. The effect of a change can be determined in from three to five minutes, and no great quantity of material of wrong composition can pass on to the bins; and even this quantity will become more thoroughly mixed in its subsequent treatment and cannot exercise much influence on the entire mixture.

Three 6-ft. x 22.5-ft. Smidth tube mills are used for fine grinding. A screen test of the tube-mill product shows 95 per cent passing a 100-mesh screen, which has been standard practice at this plant for over a year. The tendency is in favor of still finer grinding, however, and the probability is that all will be ground through 100 mesh.

Two Allis-Chalmers rotary kilns, 8 ft. x 125 ft., are fired with powdered coal delivered by blast through two 6-in. feed pipes. The fuel consumption is about 110 lb. of coal per barrel of cement. The total consumption of coal for drying and clinkering is about 130 lb. per barrel. Southern Colorado slack is used, dried in a Ruggles-Coles dryer and ground in Williams and tube mills. The Williams mill grinds about 86 per cent through 20 mesh and 40 per cent through 100 mesh; the tube grinds about 94 per cent through 100 mesh.

The provision for clinker storage is one of the features of this plant, a large area with concrete walls and floor being reserved for this purpose. The clinker is elevated from the kilns and distributed over the storage yard by a link-belt bucket conveyor running on a 100-ft. truss beam supported by steel towers. Beneath the floor are three lateral tunnels connecting with a main tunnel leading to the finishing unit. Hoppers are placed in the floor at suitable intervals along the lines of the tunnels, and through these the clinker is drawn into scale cars in which it is weighed and trammed to the finishing department.

A weighed quantity of gypsum is then added from a scale hopper and the weight checked on the second beam of the tram car. The whole weight is then checked on platform scales. The quantity of gypsum added is variable, but amounts to about 12.5 lb. per barrel of cement, which gives about 1.5 per cent SO_3 in the finished product.

In the finishing end Smidth comminuters and tube mills are used, there being two of each. The comminuters grind 88 per cent through 20 mesh and 40 per cent through 100 mesh; the tubes give a finished product of 98 per cent through 100-mesh and 82 per cent through 200-mesh screens. One of the advantages of clinker storage is noticed in the increased capacity of the machines used for fine grinding. When grinding weathered clinker the tubes will handle up to 20 per cent more material than when fresh clinker is used.

For the storage of finished cement four stock bins of 1250 barrels capacity each are placed in the packing house. Each bin is controlled with the usual tests before being released for packing and each car shipment is similarly tested. The usual routine test is applied at various stages in the process. The cement has an initial set in about 2.5 hours and final set in 5 hours. The boiling test is applied for 24 hours and the pats show no deterioration. A sulphur determination is made on the finished cement twice daily. The following figures show average tensile strength tests:

	24 hr.	7d.	28d.	90d.
Neat	350	650	800	850±
Sand (1:3)	...	290	325	375

The finished cement analyzes in per cents: SiO_2, 22.75; Fe_2O_3, 2.25; Al_2O_3, 8.0; CaO, 64.0; MgO, 0.75 to 1.1; SO_3, 1.6.

The plant is operated by electric power generated at Cañon City 15 miles further west, but the company has under consideration the installation of a gas-producer plant.

Alkali-Proof Cement.

The manufacture of cement which will resist the corroding and disintegrating action of alkali soils and waters, and at the same time develop the strength of standard Portland cement, is a new departure. The third Colorado cement plant mentioned before is that of the Western Cement Products Company, located at Minnequa, Pueblo, Col. The product is an alkali-proof cement, marketed by the Colorado Portland Cement Company, Denver.

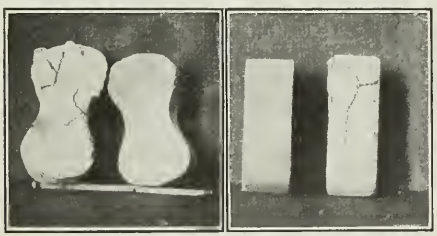

FIG. 4.—EFFECT OF STRONG ALKALI WATER ON STANDARD PORTLAND CEMENT BRIQUETS (TO THE LEFT) AND ALKALI-PROOF PORTLAND CEMENT (TO THE RIGHT).

Reference to the soil survey maps of the United States government will show the wide distribution of surface and subsoil alkali in the western part of the country. Comparatively small areas of the Rocky Mountain region and adjacent plains are free from it, and inasmuch as this region includes some of the vast reclamation projects in which cement and concrete are extensively used the importance of an alkali-resisting cement becomes apparent.

The alkali usually present in Western soils has its origin in disintegrating rocks and in deposits of gypsum, and is mainly calcium sulphate. There are also present magnesium sulphate, and the sulphate, chloride and carbonate of sodium. The action of these salts on structures of ordinary Portland cement is disastrous, causing either partial or total destruction in a comparatively short time. This action may be shown in a laboratory way by making briquets of standard Portland cement and subjecting them to the action of strong water. In Fig. 4 is shown a comparison between briquets of standard Portland and the alkali-proof cement treated in this manner for 60 days. At the end of that time the standard cement briquet is shown to be cracked and on the verge of disintegration, while the briquet of the alkali-resisting cement is sound and strong.

The cause of this action of alkali solutions is found in the composition of standard Portland cement. It contains approximately three times as much lime as silica, iron and alumina, giving an excess of lime over the quantity required for chemical combination with the silica. This excess lime is attacked by the acid radicals of the alkali, forming compounds which, in their subsequent crystallization, expand and disintegrate the mass. Once begun this action continues until, by the processes of solution and mechanical erosion, the structure becomes honeycombed with cracks and pores and finally fails entirely. A peculiar feature of this disintegration is that it may not be apparent on the surface of the work until the central portion has failed. This may be due to the fact that the excess of lime in the surface has early combined with carbon dioxide, forming carbonate which is not attacked by the alkali. Capillary attraction, however, forces the alkali solution into the center, where it accomplishes its work of destruction.

The peculiar qualities of alkali-proof cement which give it resistance to alkali are the following: It contains less than twice as much lime as silica, all of the former being chemically combined and the latter in slight excess. Thus there is no free lime to be attacked by the alkali sulphates. The alkali-proof cement is finer than ordinary Portland, giving maximum strength and minimum permeability, with little or no opportunity for disintegrating solutions to enter the mass. It has a lower specific gravity (2.96) than standard Portland cement (3.1), and hence greater volume for a given weight.

In the physical tests alkali-proof cement shows a slower setting time and develops tensile strength more slowly, but more steadily and for a longer time than standard Portland. A comparison of the two will show about equal strengths at 7 to 10 days, after which the alkali-proof cement will increase more rapidly. The following tabular statement will illustrate this and also show that the new cement is ground much finer than standard products:

	Portland.	Alkali-Proof.		
Fineness.				
Per cent through 100 mesh..	94.9	98.8	98.6	99.1
Per cent through 200 mesh..	77.3	88.6	87.0	88.7
Setting Time.				
Initial	3:22	6:00	5:40	5:40
Final	7:13	7:45	7:55	8:20
Specific Gravity	3.13	2.96	...	...
Tensile Strength.				
Neat.				
24 hr.	408	220	225	170
7 d.	703	600	490	515
28 d.	763	975	865	860
Sand (1:3).				
7 d.	272	285	340	315
28 d.	361	445	540	475

Another interesting manner of testing the alkali-resisting properties of the new cement is to make briquets with sand and varying quantities of gypsum and test their strength from time to time. It will be found that ordinary cement will develop strength as usual for a short time, depending on conditions, and then suddenly deteriorate and ultimately disintegrate. On the other hand, the alkali-resisting cement will show a steady increase in strength over a long period. These points are illustrated in the accompanying curves, Fig. 5, which will require no further explanation.

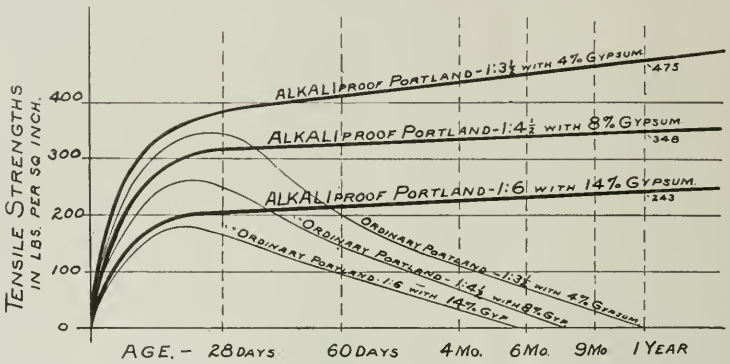

FIG. 5.—EFFECT OF ADDITION OF GYPSUM ON STRENGTH OF STANDARD AND ALKALI-PROOF PORTLAND CEMENT.

Additional comparative data are obtained by exposing briquettes to the action of air, fresh and alkali water for various periods. The alkali solution used in the tests tabulated below is about five times the strength of naturally occurring alkali waters and has the following composition:

	Grains per Gal.
$MgSO_4$	650
$CaSO_4$	900
Na_2CO_3	200
NaCl	200
Na_2SO_4	1300

In testing briquets with this solution it is renewed fortnightly to keep up the strength. Below are the results of tests of four different cements exposed to air, fresh water and alkali solution. The abbreviation "dis" indicates disintegration.

Tensile Strength Tests.

	American Portland.	German Portland.	Special German.	Alkali-Proof.
7 days.				
1:3 air	310	142	112	335
water	267	165	145	342
alkali	175	185	160	342
1:5 air	158	120	90	212
water	160	122	92	195
alkali	128	93	140	208
28 days.				
1:3 air	270	197	205	320
water	280	165	247	390

alkali	342	180	240	405
1:5 air	242	175	185	190
water	140	140	175	245
alkali	dis	127	138	235
90 days.				
1:3 air	455	268	278	367
water	405	320	237	452
alkali	dis	370	310	505
1:5 air	237	165	145	205
water	215	168	170	240
alkali	dis	175	180	245
6 months.				
1:3 air	465	335	270	440
water	415	335	245	490
alkali	dis	dis	215	480
1:5 air	255	175	155	205
water	225	180	175	245
alkali	dis	dis	dis	250

It will be observed that each of the ordinary cements disintegrated at or after 28 days, while the other remained sound. Another peculiar fact noticed from a study of several thousand tests is that just prior to disintegration the standard Portlands show a temporary increase in tensile strength.

Process of Manufacture.

Alkali-proof cement is a mechanical mixture of cement materials, and in this one respect resembles pozzuolan cement. Both cements contain low lime and high silica, but the pozzuolan develops comparatively low strengths while the other is equal or even superior to ordinary Portland in this respect, with the additional value of resisting the attack of aklali. The ingredients used in the alkali-proof mixture are iron blast-furnace slag, standard Portland cement and a mixture, the exact nature of which is not given, but which contains gypsum and other materials. The use of this mixture gives the slag increased hydraulic value and makes the cement strong as well as resistant to alkali.

The mixing of these ingredients is controlled so as to give a cement which will pass standard specifications as to strength, while giving maximum resistance to alkali. The excess lime in the ordinary Portland and the soluble silica in the slag are determined chemically and enough slag is used to provide an excess of silica over the quantity required to hold all of the lime in combination. The ingredients are then intimately mixed and finely ground. The resulting cement does not deteriorate with storage and finds special use in the field mentioned.

The plant at Minnequa has a capacity of 500 barrels daily and is under the direction of a technical staff including Tracy Bartholomew, manager; O. P. Harpel, superintendent, and H. C. Emery, chemist. Slag is obtained from the furnaces of the Colorado Fuel & Iron Company, being granulated at the furnace and dried, screened and ground to about 30 mesh at the cement plant. After being properly mixed the ingredients are ground in a tube mill with Colorado pebbles and "cylpebs" in different compartments of the same tube. The product has the following composition: SiO_2, 32.9; Fe_2O_3 and Al_2O_3, 13.2; CaO, 48.0; MgO, 2.5; SO_3, 1.8; and ignition loss, 0.3 per cent. It is the result of about seven years' study and experiment, during which time it has been subjected to many practical tests.

In conclusion, acknowledgment is due the members of the staff at each of the plants for their courtesy in giving the data presented herewith.

Inside amalgamation of free gold is not practised except under special conditions which seem to warrant its use. In case the outside plates become covered with a slimy film which cannot be easily removed, it may be profitable to apply inside amalgamation, with the frequent addition of mercury.

Manufacture of Carbon Electrodes.

In the London *Electrical Review* of Jan. 20 Mr. William Clacher, F. C. S., gives some details of the manufacture of carbon electrodes as carried out at the works of the British Aluminium Company, Ltd., in Greenock and Kinlochleven.

The author first gives the general methods used at Greenock. At Kinlochleven the methods have been somewhat modified, due to improvement in the plant, but the principles underlying both systems are the same. The difference in favor of the carbon produced at Kinlochleven is due to the new furnace there erected, which is of the regenerative type, giving a much higher temperature than the Greenock tunnel furnace.

The properties essential to a good carbon are: High conductivity, non-liability to crack, efficient contact arrangement between the carbon and the metal conductor.

The characteristics accompanying high conductivity are: (a) a good ringing sound when struck; (b) a high specific gravity and low porosity. The specific gravity of different forms of carbons varies thus:

Calcined anthracite has a specific gravity of.....1.80
Calcined petroleum coke has a specific gravity of....2.00
Kilned retort carbon has a specific gravity of.....2.05

Taking blocks made from these carbons with the same porosity, the retort-carbon block has the highest conductivity; the petroleum-carbon block has the next highest conductivity, and the anthracite-carbon block the lowest. This refers to anthracite calcined at 1000° C., not at 3000° C.—that is, non-graphitized anthracite.

The outline of the process for making the carbon is as follows:

1. The petroleum coke is first calcined to remove volatile matter and increase the specific gravity and conductivity.
2. The calcined material is pulverized.
3. The pulverized material is mixed with the binding medium in a steam-jacketed mixer.
4. The mixed mass is molded.
5. The block is kilned in the furnace, the kilning taking five days. After this the blocks are cooled, brushed, and stocked ready for use.

The petroleum coke is obtained in the distillation of shale oil; it is the residue left in the iron retorts. There is left in it from 5 per cent to 13 per cent of volatile hydrocarbons, which are not driven off with the heavy oils. There is also a small amount of inorganic material averaging 2 per cent. Most of the latter is in the harder parts; the softer and more porous parts are almost ashless. Mr. Clacher has analyzed pieces with a difference of over 5 per cent between the separate portions. Surface coloring he has found to indicate the presence of inorganic material; such carbons are none the less considered of lower grade.

The pieces as they come from the oil works are usually of large size. This is good for stacking purposes. There is at the same time a percentage of smalls and dust, varying with the quality of the coke, the softer coke having by far the largest amount. This is a serious matter to the Aluminium company; as the small dust chokes the calciners and is not easily worked away, only a certain amount can be added with each charge of coke.

The calciners are vertical rectangular brickwork chimney-like constructions; the coke is put in at the top and the calcined material drawn out with long rakes at the bottom. The charges are given every two hours, and a half charge is drawn every hour; 2 cwt. (101.6 kg or 224 lb.) was the charge in the Greenock calciners. The time the coke takes to travel from the top to the bottom is five hours.

The temperature in the calciner is approximately 2000° C. at its hottest part. The calcining is a very costly and, as at present carried out, wasteful process, for 30 per cent of the coke put in is burned away during the process; the volatile

matter in the coke before calcining averages 8 per cent, so that 22 per cent of carbon is used to raise the temperature to 2000° C., representing fuel at $17.50 per ton—considerably more costly than the best smokeless coal.

Calcination has been carried out in horizontal retorts; these are more expensive at first, but they are much more economical with the coke, 20 per cent being the loss usually found with them. In cases where the calcination was effected in a current of producer gas the loss was little more than the percentage of volatile matters in the material; 15 per cent was the figure obtained from 10 per cent volatile in the coke, and the temperature is nothing like as high as in the vertical retorts, not exceeding 1000° C. The reports on anodes made from coke calcined thus were of a satisfactory character; the specific gravity of the carbon was slightly less than that calcined in the vertical calciners, 1.95 being obtained.

Calcined coke was also once made by packing the blocks before entering the tunnel furnace with it, and then passing it through; the coke swelled up and the blocks thus packed were unusable.

In the vertical calciners experiments were begun before Mr. Clacher left with the object of saving the excessive loss by passing producer gas into the calciners and using that in place of the coke to get the required temperature. The work was not far advanced when he left, and he is not aware that anything on these lines has been worked at by the Kinlochleven staff.

After calcination the coke at Greenock contained 0.7 per cent of inorganic material, consisting of 0.5 per cent silica, 0.15 per cent oxides of iron and alumina, and 0.05 per cent soluble sodium salts.

At Kinlochleven the arrangements of the stores for the oil coke and the transporting and grinding machinery have been totally altered. In addition, breakers to crush the coke to the size required for calcining have been erected; vertical rotary crushers and high-speed vertical grinding mills are used, and the sieving machinery is more up to date. At Greenock the breaking of the coke was done by men with hammers.

The grinding of the calcined oil coke is done in two stages: (1) An initial crushing to pass through a ⅜-in. mesh; (2) a grinding to get the correct gristing of the powder. The gristing is an exceedingly important item; the amount of fine dust and large must be properly proportioned to get the block with the highest specific gravity and least porosity.

A good gristing is: Through 100-mesh, 40; 60-mesh, 15; 30-mesh, 20; 16-mesh, 15; between 16-mesh and 8-mesh, 10.

The cost of grinding at Greenock was from 75 cents to $1 per ton; there was a large loss of carbon in the open pan-mill and the machine for the finer grinding amounting to 7 per cent of the total. This loss is done away with when using the new machinery.

The supply of petroleum coke, a by-product in the paraffin industry, is dependent on the quantity of shale oil distilled, and this is strictly limited in amount.

In view of an expected increase in the demand for aluminium and a consequent greater need for a good carbon, a search was made for likely sources. Of retort carbon, which is used for making the furnace linings, the supply is limited to the quantity of coal gas made. Of anthracite there is an unlimited store, and provided the inorganic contents were within the limits of the supply of calcined oil coke, this was considered a possibly valuable article.

The limits of impurity allowed were 0.5 per cent silica and 0.2 per cent iron oxide; this was the average analysis of the ash contents and the kilned blocks at the time, in the year 1904.

A great amount of work was performed on this for a period extending over three years. After that the work was stopped for a time. After Mr. Clacher had left the company he continued the experimental work, and after overcoming some of the difficulties left unsolved in the Greenock factory, he patented the process (British patent No. 2071, 1909).

The following forms of carbon were treated at Greenock: 1. The returned blocks from the Foyers furnaces. 2. Retort carbon. 3. Anthracite, Scotch and Welsh. 4. Bituminous coal. 5. Graphite.

The work on (5) was carried on exclusively after Mr. Clacher had left the company.

1. The returned blocks from Foyers contained approximately 2 per cent inorganic constituents, of which a little over 1 per cent was silica and iron oxide; this was crushed to pass through an 8-mesh sieve, with the usual gristing and, after treating, the inorganic contests were reduced to 0.5 per cent. An analysis of the untreated and treated material is given as follows:

	Before.	After.
Ash	1.56%	0.53%
Soluble	0.33	0.17
Silica	0.46	0.14
Iron oxide	0.26	0.14
Oxide of aluminium	0.39	.
Difference (CaO, MgO, SO_3)	0.12	...

2. Gas retort carbon as used at Greenock contained from 2 per cent to 4½ per cent of inorganic constituents. Crushed to pass through an eight mesh, and of the usual grist, the inorganic was reduced from 3 per cent to 0.75 per cent. Analyses:

	Before.	After.
Ash	2.35%	0.68%
Soluble	0.10	...
Silica	0.91	0.20
Iron oxide	0.62	0.26
Oxide of aluminium	0.41	0.08
Lime	0.17	...
Magnesia	nil	.
Sulphur trioxide	0.11	..
Difference	0.03	...

Another analysis:

	Before.	After.
Ash	2.87%	0.71%
Soluble	0.08	...
Silica	1.13	0.16
Iron oxide	0.86	0.19
Oxide of aluminium	0.60	0.36[1]

3. Scotch Anthracite.—The seams tested contained from 4 per cent to 12 per cent inorganic. Analyses are given of some purified; in this case of somewhat smaller grist, the whole passing a 16 sieve:

	Before.	After.
Ash	9.24%	1.81%
Silica	5.00	0.83
Iron oxide	1.06	0.22
Oxide of aluminium	2.02	...
Lime, magnesia sulphate and soluble	1.16	0.19

	Before.	After.
Ash	4.99%	1.08%
Silica	2.47	0.49
Iron oxide	0.46	0.08
Oxide of aluminium	1.69	0.19
Lime	0.09	
Magnesia	0.05	
Sulphur trioxide	0.08	0.32
Difference	0.15	

Ground to pass through a 60 mesh the totals were reduced in proportion. Analyses:

	Before.	After.
Ash	6.50%	1.25%
Soluble	0.17	included in diff.
Silica	3.55	0.38
Oxide of iron	0.88	0.05
Oxide of aluminium	1.55	0.31
Difference	0.35	0.51

[1] Soluble and oxide of aluminium.

With Welsh anthracite he got from a seam analyzed:

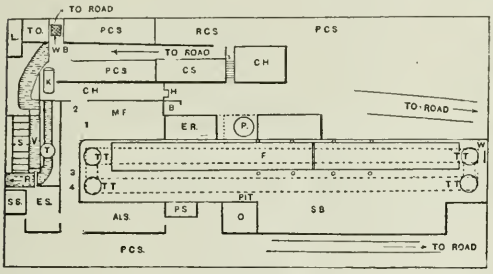
	Before.	After.
Ash	2.08%	0.57%
Silica	0.78	0.20
Oxide of iron	0.32	0.12
Oxide of aluminium	0.43	0.12
Soluble and difference	0.53	0.13

The material was milled to pass a 16 mesh.

4. With a good bituminous coal containing 3 per cent of ash the silica was reduced to less than 1 per cent. The iron oxide was not removed, and work was discontinued on that account.

The process used was a hot digestion with a strong caustic solution and the removal of the silicates, sparingly soluble in caustic, with a weak acid solution—iron oxide being subsequently extracted.

The accompanying diagram is a sketch plan of the general arrangement of the carbon factory; *PCS* is the petroleum coke stock; *RCS* retort carbon stock; *CH*, calcining house; *GH*, grinding house; *H*, hoist; *MF*, molding floor; *F*, tunnel furnace; *TT*, turntables; *W*, winch; *SB*, stock finished blocks; *PS*, stock pitch; *CS*, coal; *B*, boiler; *ER*, engine-room;



SKETCH PLAN, SHOWING GENERAL ARRANGEMENT OF CARBON FACTORY.

P, producer; *L*, laboratory; *TO*, time office; *ES*, engineers' shop; *SS*, smiths' shops; *ALS*, aluminium stock; *O*, offices; *S*, flight of stairs; *V*, overflow; *R* runaway from turbine; *T*, water turbine; *WB*, weigh bridge; *K*, kilns for drying carbon. 1, 2, 3 and 4 represent the position of the machines, etc., shown in Figs. 1 to 4 respectively.

From the grinding mills the fine powder is taken away to the store hoppers, from which it is transferred to the Werner and Pfleiderer mixing machines; these are seen in Fig. 2 and are of the steam-jacketed kneading type, with reversing gear for changing the direction of motion. The temperature of the mixture when ready for discharging is 90° C. In the mixers shown the tipping is effected by means of an upright screw; in the large new mixers for Kinlochleven a worm quadrant and screw is used in place of the upright screw. The mixers in the illustration hold a charge of 300 lb. of mixture.

The hopper for weighing the carbon is seen over the right-hand mixer and the pitch-weighing tank over the left-hand mixer. The amount of pitch used is 22 per cent of the mixture; it is a medium hard brand and has volatile constituents to the extent of 50 per cent, as volatile is determined quickly; only 40 per cent volatile goes away during the slow kilning.

The tar used for making the linings for the electric furnace is much softer, containing up to 60 per cent volatile as determined by the quick method. This lining for the furnaces was made at the mixers in Greenock, bagged, and sent to Foyers, where it was heated and rammed in the furnaces at the side and bottom and then baked with current passed through before charging the furnaces with the electrolyte. The life of the linings varied from a few days to months. Latterly the mixture for the furnaces was made at the electric reduction works, saving the trouble and expense of the reheating.

For making the tar to the required degree Mr. Clacher used an instrument for measuring its fluid quality at the temperature of mixing (115° C.), the time a given weight took to run out of an orifice giving the indication required. He found tests so performed were usually in agreement with the volatile determination and a test of the fluid nature is of more value as a criterion for the binding material in the tar than is the percentage of volatile matter in the semi-liquid.

The bending point of a slab of pitch 3 in. long and ½ in square is a very good test for the pitch. This test is certain;

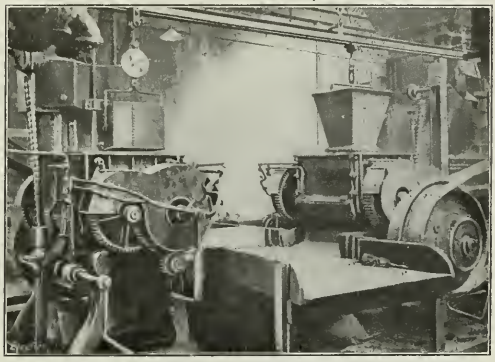


FIG. 1.—MIXING MACHINES.

the determination of the volatile content is anything but certain. Mr. Clacher has found that when the greatest care is taken the limit of accuracy of volatile determination is such that a determination of that kind is not a standard of value.

Fig. 2 shows the arrangement of the mixing and molding floor. On the right-hand side are two melted-pitch tanks; they are wrought-iron vessels, steam heated by internal coils. The pitch is lifted up by means of a small windlass and emptied into the tanks as required. A third tank was afterward added; this was a steam-jacketed vessel and worked more satisfac-

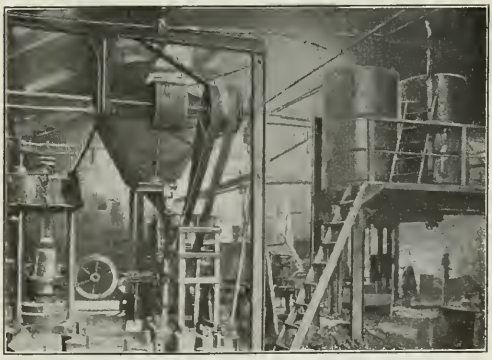

FIG. 2.—MIXERS AND PITCH TANKS.

torily than the two shown; the leakage of the joints in the coils caused frothing and overflowing of the tanks heated with the internal coils. In the center are the two mixers and the store hopper containing the carbon; on the left hand are the hydraulic molding machine and some of the molded blocks.

The mixture when tipped from the mixer to the platform is transferred in scoops to the container of the mold, which is in the center of the machine. When the mold is full the water valve is opened, the container rises and the block is formed.

When the gage registers 1 ton to the square inch the valve is shut and the runaway valve opened, the container lifted and the block discharged; it is taken away and put on the floor, there to remain for a day to harden previously to being packed in the trucks for putting through the furnace. Half a ton to the square inch will form a good block. One ton is usual, and as much as 4 tons has been used.

It is not possible to make a good block with mixture that is cool, and arrangements are made to work with as little stock of mixture as possible. The capacity of the machine illustrated was 40 blocks an hour. The Kinlochleven machine is more complicated and is designed for a larger output.

The blocks are 10 in. square, with cutaway corners, and are

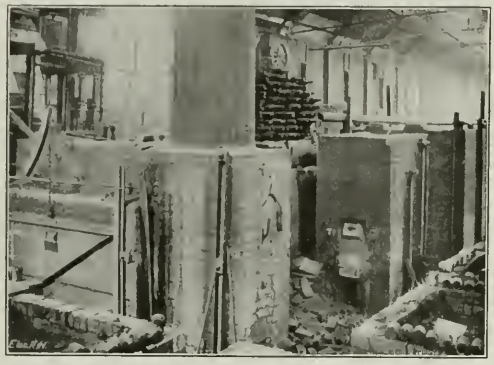

FIG. 3.—HEATING END OF FURNACE.

12 in. high. Those shown in the illustration are flat topped. This has been improved and for some time all the blocks have been made with the top rounded. The top of the block, efficient only as a means of making contact, is thus reduced in weight, and consequently a rounded-top block of equal weight to a square-top block has more carbon usable for the reduction of the alumina

The contacts seen in the blocks are of mild steel and are molded in the blocks, the internal end being forked; the forks are thoroughly cleaned and coated with pitch previously to being put in the clamp for molding. It is noticeable that the contacts are not central in the block. When the contact is made at the furnaces the point of suspension becomes central and the blocks hand vertically without strain.

The form of contact shown is the best between the carbon and the metal; but these are very expensive to have in stock. A large number is required, and the wear and tear on them is great. The later forms of contact are made by screwing the metal into a molded thread in the block; the number of contacts required in stock is much lessened and the wear and tear comparatively inappreciable.

The weight of a block before kilning averages 70 lb. with the claw; after kilning, 66 lb. with the claw. The claw weighs 8½ lb. The loss of 4 lb. in the block corresponds to 8 per cent on the block and 40 per cent on the pitch used. The arrangement of the pitch tanks at Kinlochleven was much altered and in no way resembles the Greenock arrangement. This was on account of the much larger output that was expected.

When made the blocks are stored till they are hardened somewhat and are then placed in the trucks for calcining. At Greenock the blocks were stored on the molding floor; a few days' stock was kept.

The trucks seen in Figs. 3 and 4 are oblong and made of firebrick; they are mounted on bogies. The blocks are placed, 42 in number, in a truck and are packed with the fine ashes free from dust; the metal contacts are covered with fireclay covers and the fireclay covers are completely hidden with the ashes. The truck is then pushed into the furnace and at the same time a truck with the kilned blocks is pushed out of the other end of the tunnel by the same movement, which moves each truck in the furnace one stage on. A hydraulic ram is used for this purpose. As soon as the truck with the unkilned blocks is in and the truck with the kilned blocks out the iron furnace doors are dropped and the furnace is at normal again.

Producer gas is the fuel used for heating the furnace, this being made in a Mason producer; the coal found best for that purpose was a Lanarkshire singles containing 3 per cent to 5 per cent of inorganic and 30 per cent volatile constituents; the analysis of the gas made is:

Carbon dioxide	4.0
Carbon monoxide	22.0
Hydrogen	16.0
Methane	4.0
Oxygen	2.0
Nitrogen	52.0
	100.0

The flues from the producer to the furnace require cleaning once every eight days; the regulation of the quality and quantity of the gas also requires attention. When Mr. Clacher went to Greenock the producer was consuming 40 tons of singles a week. By regulating the feed and the steam and the air he got the consumption down to 27 tons per week. At the same time a more constant temperature was produced.

The furnace is seen in Figs. 3 and 4. It is 200 ft. long. On either side are four gas valves. These are regulated to give an even temperature over the middle of the furnace. The escaping gases heat the incoming trucks and the outgoing truck is somewhat cooled before being ejected. The maximum temperature at the top of the truck is usually 1150°, at the bottom of the truck 700° C. The latter is the temperature to which the bottoms of the anodes made at Greenock are kilned. This is

FIG. 4.—TUNNEL FURNACE AND ROW OF TRUCKS.

doubtless a disadvantage for the purpose to which the furnace is now applied—the calcination of alumina to be used at the electric furnaces.

The furnace at Kinlochleven is built of firebrick and is of the type used at Witton, in that it is regenerative, the chambers in which the articles kilned are cooling being used to heat the air for the combustion in the hot chambers; the temperature normally attained as a maximum is said to be 1400° C., and the

ame time is taken for the cycle of operations as at the Green-ck factory—5½ days. The chambers are filled with the boxes ontaining the blocks, which are packed as at Greenock with ne ashes; they are stacked one above the other in the cham-er. The boxes are of fireclay and are made at Kinlochleven. When the chamber is filled to the requisite capacity the open-ng is sealed with brickwork, and this chamber is then made he last in the circuit of the gases passing through it previous o entering the chimney flues. The accompanying plan, Fig. 5, ives an idea of the arrangement of the chambers.

The blocks kilned in this furnace are said to be much more fficient at the electric furnaces than the Greenock kilned ones.

At Foyers during the past few years the Greenock blocks ave a yield of 1 lb. aluminium for 0.7 lb. carbon used; the ost that is expected is 0.64 lb.

A great amount of trouble has sometimes been caused by the urning of the blocks by the air at the electric furnaces; this

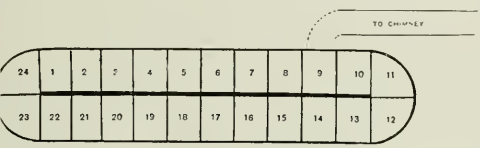

Fig. 5.—Plan of Regenerative Furnace.

erious reduction of the efficiency of the carbon was gone into, nd many coatings were given the blocks to prevent the oxida-ion, whitewash among others. Mr. Clacher has reason to hink this difficulty is solved. Cracking of the blocks at the lectric furnace is a trouble due to the block not being to tandard. A block should last from 100 hours to 140 hours, and vhen conditions are normal in the furnace the time factor is nost valuable. When blocks last less than 100 hours they are ot classed good.

The specific gravity of the Greenock blocks was 1.63 after ilning, and the porosity 20 per cent; different parts of the Greenock blocks had often different porosities and considering he difference in temperature between 1150° and 700°, the tem-eratures at the top and floor of the truck, this is not to be vondered at. Before kilning the specific gravity was 1.53.

Mr. Clacher experimented with the making of blocks from a ery heavy pitch with less than 40 per cent volatile matter. Blocks thus made in a gas-heated mixer were harder than the sual block; their conductivity he did not have tested.

[In connection with this article it may be interesting to refer o some progress which is reported as having recently been nade in the manufacture of large amorphous carbon elec-rodes. It is reported by reliable correspondents that in Euro-ean electric steel furnace plants amorphous carbon electrodes n sizes up to 600 mm (24 in.) diameter are in use and that no roubles due to cracking of electrodes are experienced.]

The Arbuckle process of ore treatment as used in South Africa is thus described by H. A. White, in a paper read before the S. A. Association for the Advancement of Science: It nvolves the treatment of the pulp as a whole without sepa-rating sand from slime, and thus solves that difficulty by the nethod of evasion. The pulp, mixed with about three times ts weight of weak KCN solution, is agitated by an air lift in deep tanks with conical bottoms. After about 20 hours' agita-tion, the whole pulp is transferred to a separating apparatus, where the solid portion, with about 25 per cent moisture, is drawn off for further washing, and the clear solution sent to the precipitation tanks. The drawback lies in the agitation of the whole pulp for the entire period, when perhaps the slime portion would not require so long an agitation. Nevertheless, it is possible that owing to decrease in working costs in larger units, greater skill in handling material, and other important reasons, this method, with modifications, may become of im-portance in South Africa.

A New Form of Gauze Electrode for the Rapid Electrolytic Determination of Lead and Copper.

BY R. C. BENNER.

The present trend for lead and copper determinations being toward the use of electrolytic methods, any increase in rapidity, simplification or lightening of labor in the use of this method is of vital importance.

When the interfering elements are removed and the deposition is carefully made, the electrolytic determination of copper is generally recognized as the standard, and is, as well, the most accurate of the various methods employed in technical work. The determination of lead by this method until recently has been more likely to error than that of copper, as the PbO_2 deposited was likely to have a varying composition depending greatly on the conditions of precipitation.

Every person who has made a quantitative, electrolytical determination of lead has found necessary the use of some factor other than the theoretical. This has made the determination of an arbitrary factor necessary in each case. When the peroxide of lead is deposited on the inside of a platinum dish it is possible to ignite the PbO_2, changing it to PbO, in which form it can be weighed with faultless results.[1]

When the deposition is made on the gauze electrode it is impossible to ignite over the Bunsen burner, as some of the PbO is volatilized, or some of the PbO_2 remains undecomposed,

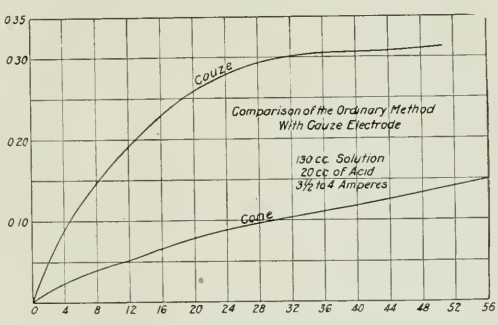

Fig. 1.—Comparison of ordinary electroanalytic method with the use of gauze electrode.

giving low or high results respectively. This may be obviated with the gauze electrode by igniting in a muffle below a red heat (500° C.) or in a small electric furnace made for the purpose.

Recently Sand[2] has been enabled to deposit the peroxide of lead in such a condition that the error caused by the use of the theoretical factor can be neglected when the amounts of lead found in a 0.5 gram sample of ore are taken. This he accomplished by means of a rotating cathode and gauze anode, depositing the lead from a strong nitric acid solution, free from NH_4NO_3 and the oxides of nitrogen, at a temperature just below the boiling point (94-97° C.), using a current of 5 amperes. When the deposition is made in this manner the use of the factor 0.8651 gives correct results. This factor is so near the theoretical (0.866) that the latter can be used without error larger than other errors involved.

The simplest form of apparatus in use at the present time consists of the two ordinary platinum electrodes, with which it takes from five to ten hours to deposit the amount of copper found in 0.5 gram of ore. The shapes of these electrodes have been modified indefinitely but serve essentially the same purpose. The rapid precipitation of the various elements in such a form that they can be weighed accurately is possible with

[1]Treadwell Analytical Chemistry, New York, 1904, Vol. 2, p. 140.
[2]Chemical News, 100-269.

several different forms of apparatus, all of which are dependent on the necessity of agitating the electrolyte, so that as long as there is any metal in the solution some of the metallic ions will be touching the cathode at any instant and be deposited.

In order to accomplish this, Smith, at University of Pennsylvania, rotated the anode, while Gooch, at Yale, rotated the cathode. Both of these forms, however, while giving a rapid method for obtaining excellent results, possess the great disadvantage of requiring more or less complicated pieces of apparatus with which to agitate the electrolyte, and more attention than the ordinary apparatus in use with the slower methods.

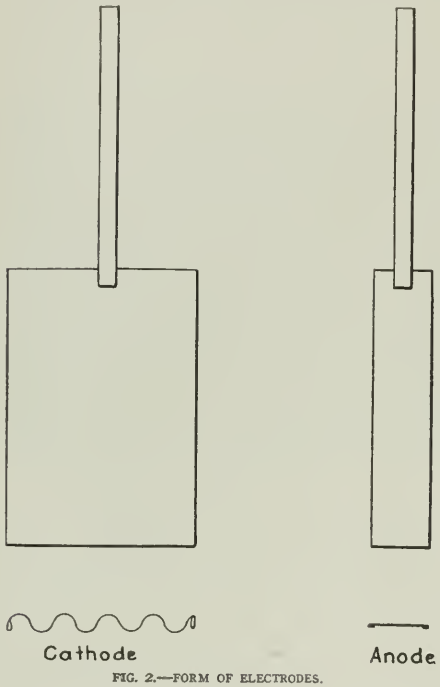

FIG. 2.—FORM OF ELECTRODES.

The advantage of rapidity for technical laboratories is more than counteracted by the disadvantage presented in this complexity. The need, then, of apparatus which combines the advantages of both and eliminates their disadvantages, becomes evident. It recently has been possible to accomplish this to a certain extent by the use of a cathode made of platinum wire gauze.[3]

The gauze electrode makes possible the use of stationary electrodes as simple as the most simple foil electrodes, at the same time allowing the deposition of copper and lead in a much shorter period than in the case of the ordinary electrodes. This will be seen by examination of the curves, Fig. 1.[4]

The deposition on the gauze electrode, even though it can be made much more quickly than by the old method, cannot equal the rapidity of the rotating cathode or anode. The nearest approach to the rapidity of the gauze electrode when stationary electrodes are used is found in the device of Messrs. Guess and Haultain. This consists in the use of very light electrodes, 1.2 grams in weight, and the precipitation of small quantities of copper (less than 0.1?) in the presence of a nitro compound. Using a current of 1.5 amp it takes from 1.5 to 3 hours to make a deposition. The apparatus is very compact and handy for this work and has been put into use by many assayers through the western United States.

As this apparatus has such an extended use it seemed desirable to design an electrode which would be suited for use in connection with it and yet possess some of the advantages of the cylindrical gauze electrode employed for our previous work on lead and copper. The electrode designed and used in our experiments is shown in Fig. 2 and consists of sand-

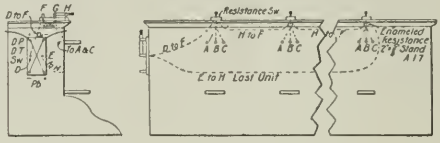

FIG. 3a.—WIRING ARRANGEMENT.

blasted gauze. These electrodes can be connected by the method shown in Fig. 3, *a*, *b*, and *c*, which is used in the Guess-Haultain cabinets, or by the arrangement shown in Fig. 4, used by Dr. W. H. Ross and the author for general electrolytic work. By this arrangement it is possible to use each deposition cell independently. In Fig. 4, R_1, R_2, R_3, are small resistance boards of about 10 ohms, made of nichrome resis-

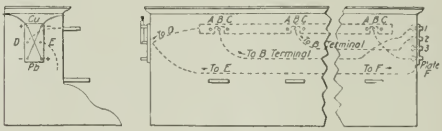

FIG. 3b.—WIRING ARRANGEMENT.

tance wire, manufactured by the Driver Harris Wire Co., of Harrison, N. J. This is the most satisfactory resistance wire with which the author has had experience. Each deposition cell has its resistance box for independent regulation. The amount of current for the system as a whole is regulated according to circumstances. The switches, S_1, S_2, S_3, are the main switches for opening and closing the circuit for the

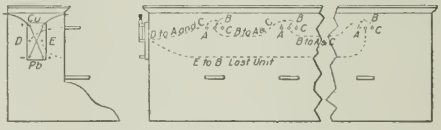

FIG. 3c.—WIRING ARRANGEMENT.

operation of each cell. When a cell (C_1) is in operation alone, the other switches S_2 and S_3 remain open when S_1 is closed. AS_1 is the ammeter switch. By closing AS_1 and opening S_1 we get the ammeter reading for that particular cell. Closing VS_1 we get the voltmeter reading. The terminals C_1, C_2, C_3, are those of the Guess-Haultain apparatus with very slight modification, as shown in Fig. 5. These were slightly more satisfactory, due to the fact that our electrodes had much thicker handles than those used with the apparatus mentioned. The voltmeter and ammeter readings may be obtained in the same manner for any cell when any number of cells are in operation.

Process for Lead Ores.[5]

Since it is possible to remove the sulphur from galena, as well as from some other sulphides, in the form of H_2S by warming with HCl (2-1), it is convenient to use the following method for those galena ores containing no interfering sul-

[3] Stoddard, J. Am. Chem. Soc., 31, 385 (1909); Palmer and Palmer, Trans. Am. Electrochem. Soc., 15, 489 (1909); Benner, J. Ind. and Eng. Chem., Vol. 2, No. 5 (May, 1910); Benner, Ibid., Vol. 2, No. 8, (Aug., 1910); Frary, 17th Gen. Meet. Am. Electrochem. Soc., Pittsburg, May 5-7, 1910.

[4] Palmer and Palmer. Ibid.

[5] J. Ind. and Eng. Chem., Vol. 2, No. 8.

phides. Weigh out from 0.5 to 1.0 gram of finely pulverized ore, warm with 15 to 20 cc. HCl (2-1) until completely disintegrated and all of the sulphur evolved as hydrogen sulphide, but not to such concentration that lead chloride crystallizes out, causing bumping. Then add 20 cc. concentrated HNO_3 and boil until all of the HCl is expelled and the nitric acid has a volume of about 10 cc. Dilute to 75 cc. and electrolyze in the usual manner. Those ores containing sulphides which render the preceding method impossible are disintegrated with HCl and HNO_3, then treated with 15 cc. H_2SO_4, and the solution evaporated until heavy white fumes of sulphuric anhydride are evolved. After cooling, 50 cc. of water are added

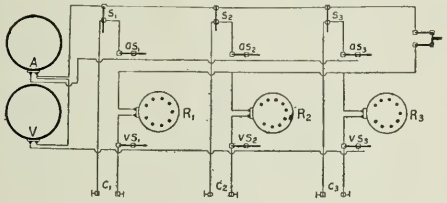

FIG. 4.—ARRANGEMENT OF AUTHOR.

and the solution boiled until all of the basic iron sulphate is dissolved. Dilute the solution to 20 cc., filter and wash free from sulphuric acid, washing by decantation as much as possible. The lead sulphate is then washed, with the smallest possible amount of water from the filter into the beaker containing the bulk of the sulphate washed by decantation. Pour 10 cc. of a warm saturated solution of ammonium carbonate through the filter, receiving it in the beaker containing the sulphate of lead, and warm until all of the sulphate is converted to the carbonate. The lead carbonate is then filtered through the same paper, washed with water until free from ammonium carbonate, dissolved in 40 cc. HNO_3 (1-3), the filter paper washed free from lead, and the solution electrolyzed in the usual way. The following results on a lead ore containing copper show the accuracy of the method.

Analysis of the ore by ordinary methods: Ore No. 1, 2.7 per cent copper and 21.5 per cent lead; ore No. 2, 2.28 per cent copper and 22.2 per cent lead. Electrolytic determination of lead: No. 1, 21.52, 21.51, 21.59; No. 2, 22.2, 22.06 per cent.

Where it is desired to do away with the use of the factor, and at the same time use the electrolytic method of determination, it is possible to do so by igniting the gauze electrode on which the peroxide of lead has been deposited, in a muffle or small electric oven at a temperature of about 500° C. The following table shows the accuracy of this modification of the electrolytic method when a C. P. lead solution is used:

Lead taken.	Lead found.
0.2509	0.2511
0.2500	0.2506
0.5018	0.5035
0.5018	0.5026
0.7527	0.7518

The lead peroxide can be readily removed from the gauze electrode by means of dilute nitric acid containing a small amount of potassium nitrite.

Process for Copper Ores.[6]

Dissolve from 0.5 to 1.0 gram of the ore, containing none of the interfering elements, in nitric or nitro-hydrochloric acid. When aqua regia is used, or if lead is present, sulphuric acid is added and evaporation continued until the heavy white fumes of sulphuric anhydride are evolved. The excess of sulphuric acid is neutralized with ammonia, and 3 cc. of concentrated nitric acid added. Providing no sulphuric acid is added it is necessary to evaporate to only 3 cc. In either case the solution is diluted to 75 cc., transferred to a tall battery beaker without filtering (if the residue does not settle readily it is better to filter), and the copper deposited by means of a current of 5 to 8 amperes and 3 to 4 volts. If the deposit is black or dark colored it is dissolved in 3 cc. nitric acid and redeposited in the same way. This redeposition is, as a rule, easier and quicker than filtering. Results are as accurate as with the older method if proper care is taken.

[6]J. Ind. & Eng. Chem., Vol. 2, No. 5.

Process for Copper Slags.

In case of slags and other low grade material it is necessary to select a method of disintegration suited to the particular material in hand. Slags, which always give large quantities of gelatinous silica and contain small percentages of copper, give the most accurate results when disintegrated with nitric acid, followed by hydrofluoric and sulphuric acids. After evaporation until heavy white fumes are evolved the analysis is finished as for ores. Redeposition is more frequently necessary with low grade material than with high, but in all cases it is more accurate and rapid than filtering.

Elements which interfere, and at the same time are likely to occur in copper ores, are arsenic, antimony, lead and bismuth. The separation of antimony and bismuth from copper was tried under the preceding conditions, but without success. Arsenic in small quantities will not be deposited with the copper, but in amounts about equivalent to the copper present begins to be deposited with the last of that metal. This can easily be removed by dissolving the deposited copper and reprecipitating under the same conditions as before.

The removal of the interfering elements by chemical means can be accomplished by the following method: The ore is disintegrated with nitric and hydrochloric acids, and then treated with 5 or 6 cc. of sulphuric acid and evaporated until heavy white fumes are evolved. Cool and dilute with water to about 150 cc. boiling to insure complete solution of the basic sulphate of iron, and adding a few drops of hydrochloric acid if silver is present. Filter and wash with water containing a little sulphuric acid. The filtrate is now heated to boiling and saturated with hydrogen sulphide, allowing the solution to cool during the process. The precipitated copper is filtered and washed with water containing hydrogen sulphide. Rinse the precipitated sulphides from the filter paper into a beaker, using as little water as possible, and warm with a little colorless sodium sulphide to remove antimony and arsenic, and again filter through the same paper, using wash water containing sodium sulphide. Bismuth is now removed from the copper by warming the mixed sulphides with a solution of potassium cyanide made alkaline with ammonia. This dissolves the copper, leaving the bismuth. Filter, and boil the copper solution with nitric acid to destroy the cyanide, and electrolyze in the usual manner.

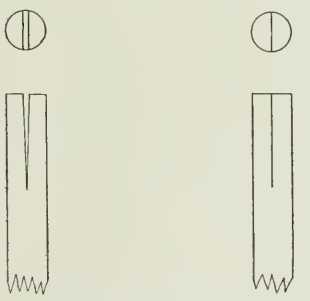

FIG. 5.—TERMINALS.

Copper Ores Containing Large Amounts of Iron.

When copper ores contain large amounts of iron it is impossible to deposit the copper successfully from a nitric acid electrolyte, as frequently before the deposition is completed a resolution of the copper often takes place from the combined action of the iron salts and the nitric acid. This phenomenon is well described by Classen in his work on electrochemical analysis, as observed by him and others.[7, 8] "Three grams of

[7]Fairlie and Boon. Electrochem. & Met. Ind., Vol. 6, p. 58.
[8]J. Am. Chem. Soc., Vol. 32, No. 10.

a sample of copper containing from 40 to 50 per cent iron were taken, dissolved, diluted to 150 cc. and electrolyzed in the presence of 3 cc. of nitric acid, with a current of three amperes. As the precipitation of the copper began the solution took on a brown color. As it proceeded suddenly the solution was decolorized together with the solution of the copper, after which the electrolyte gave only a slight test for ferrous iron."

"This is explained as follows: During the electrolysis the hydrogen liberated reduces the iron to ferrous form, which with the decomposition products of nitric acid, forms the unstable compound $xNOyFeSO_4$. As long as the reduction of the iron takes place the precipitation of the copper continues, but as soon as this reaction reaches an equilibrium under the existing conditions, the unstable compounds suddenly decompose with the resolution of the copper and the oxidation of the iron, which is indicated by the decolorization of the solution."

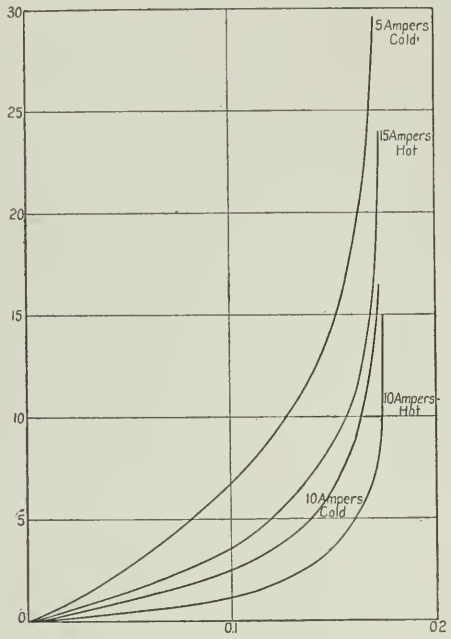

FIG. 6.—DEPOSITION CURVES FROM HOT AND COLD SOLUTIONS.

Blaisdal and Harrison[8] have shown that it is possible to prevent the formation of nitrous acid and consequent solution of copper by the addition of 5 grams of urea to the acid solution of copper before electrolysis.

Figs. 6 and 7 give the rate at which lead and copper are precipitated with the electrode shown in Fig. 2 and under the conditions used for the precipitation of these elements in ores. Each point determined on the curves was made as a separate determination with a new solution containing the same amount of copper or lead in each case.

The following points may well be observed in the electrolytic determination of these metals:

1. Always keep the cathode completely covered by the electrolyte.

2. Care must be taken not to stop the electrolysis until the precipitation is complete. The time of deposition varies with different electrodes, volume of solution, amount of metal in solution, etc., even if the current is the same in each case. These facts are especially true with rapid methods and with the gauze electrode in particular.

3. Dissolve and redeposit all dark colored copper precipitates, as frequently they give high results. This may be due to the oxidation of the copper, or to the presence of interfering elements.

4. Use great care in adjusting the electrodes so that the current density is as nearly the same as possible at all points. When the density is higher at some points than at others it is likely to cause decolorization of the copper at these points.

5. In selecting gauze electrodes choose those which will allow the best circulation of the electrolyte and as large a surface as is convenient.

6. Under some conditions the deposited copper is likely to be spongy but will give good results if the deposit is not brushed off. Handle the electrodes in this case with the same care used with those on which lead peroxide has been deposited.

7. Do not try to deposit more than 0.2 to 0.3 gram of copper or lead, as such deposits are not as good as when small amounts are used.

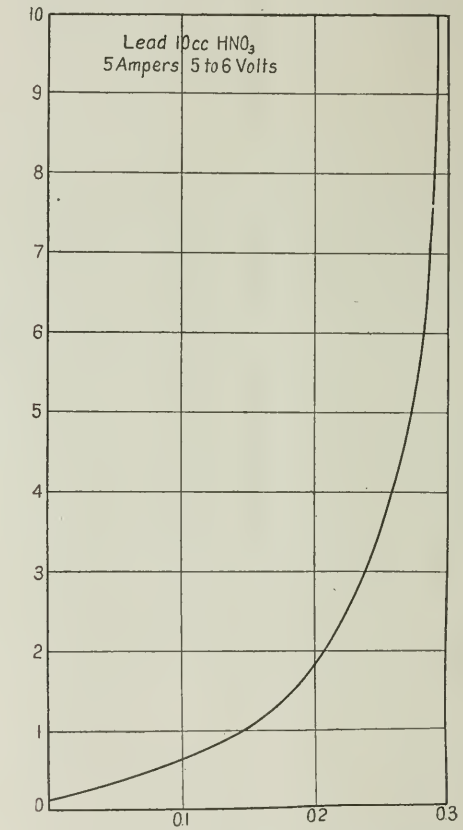

FIG. 7.—DEPOSITION OF LEAD. (ABSCISSAS REPRESENTING GRAMS PbO_2).

8. Do not allow the electrolyte to boil away, as the concentration of the acid is likely to cause the solution of the metal.

University of Arizona, Tucson.

American Society of Mechanical Engineers.—The sixty-third meeting of the American Society of Mechanical Engineers will be held in Pittsburgh, Pa., from May 30 to June 2. This is the first meeting of the society in Pittsburgh since 1884. Col. E. D. Meier, of St. Louis, is president this year.

Chemical Engineering in the Manufacture of Metallic-Filament Lamps.

It is unnecessary to emphasize at this place that the progress in modern lighting methods has been rendered possible essentially by the work of the chemist. This is true both for electric incandescent and arc lamps as well as for gas lamps.

In the manufacture of incandescent lamps the adventure of the metallic-filament lamp (first osmium, then tantalum, finally tungsten) was revolutionary after the carbon lamps had reigned supreme for so many years. In the preparation of the tungsten filament chemical engineering plays a large part in all the different processes devised for this work. Undoubtedly the most important recent advance is the method developed in the research laboratory of the General Electric Company under the direction of Dr. W. R. Whitney for producing ductile tungsten, as noted in an American Electrochemical Society paper of one of the inventors, Dr. C. G. Fink (our vol. VIII, p. 340).

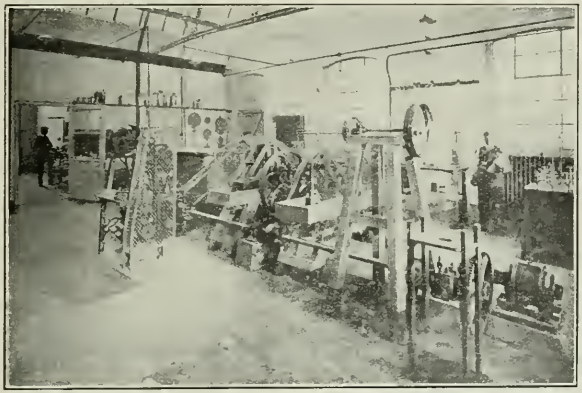

FIG. 1.—CHEMICAL DEPARTMENT, SHOWING MECHANICAL MIXERS IN FOREGROUND.

Nevertheless the older methods of making tungsten filaments are still of great importance and considerable interest and in view of the secrecy which generally surrounds metallic-filament lamp works some notes on a British tungsten-lamp factory—the Brimsdown Metal Lamp Works—are particularly interesting. They are taken from the London *Electrician* of Jan. 27 and London *Electrical Engineering* of Jan. 26.

The process of Dr. Kuzel in which the colloidal state of tungsten is made use of is employed in this factory. The filaments in the Brimsdown metal lamps are produced from colloidal tungsten, and not from tungsten powder. The colloid is mixed with water in the chemical department, and the solution is placed in bottles which are clamped securely in frames and rotated slowly through gearing by a small motor. These frames are shown in the foreground in Fig. 1. The process is one that ensures the thorough mixing of water and the colloidal tungsten.

The mixture is then reduced to a plastic state by another process and passed between water-cooled rollers. From these rollers it emerges as an extremely thin sheet of metal, and is twisted up and is pressed into a cartridge.

This cartridge is passed into the squirting department, a general view of which is given in Fig. 2. The actual squirting of the filament is carried out both by hand pressure and hydraulic pressure. In the illustration (Fig. 2) three hydraulic presses will be noticed on the right and six hand presses on the left. The material is squirted through diamond dies, which vary in diameter according to the candle-power and voltage of the lamps for which the filaments are intended. The filaments for the lamps of ordinary size are finer than a human hair, ranging from about one-fortieth to a millimeter upward in diameter.

The squirting is carried out vertically downward, and the thin material is received on a large white card, which is moved backward and forward so as to spread the filament over the card. When the card is full it is passed on to benches in another part of the same shop, and in the soft state the filaments are divided off into U-shaped loops. They are then laid in metal trays, which are placed in baking ovens. In these ovens the moisture is driven off and the filament loops are then cut off to standard lengths.

The forming department of the works is one of the most interesting, because it contains a quantity of special apparatus which has been designed and manufactured by the company's staff. This apparatus is fitted up in units, each of which is complete in itself, and mounted in groups on the benches, which run transversely across the shop.

The filament-forming process consists of a chemical and electrical treatment of the filament under a glass bell. The U-shaped filament is held in two clips, which serve both as supports and terminals for the testing circuit. A tungsten wire is hung at the bottom of the U as a weight. The bell is then partially exhausted and ammonia gas is admitted in a certain quantity into the bell. An exhausting tube is also provided to extract the air and other products during the forming process. Current is applied to the filament, and the voltage is gradually raised from practically nothing to 50 per cent above normal. This is controlled absolutely automatically by a motor, so that the current is gradually increased up to a certain value and then switched off. During this process the filament changes its form materially due to the weight of tungsten wire attached to it.

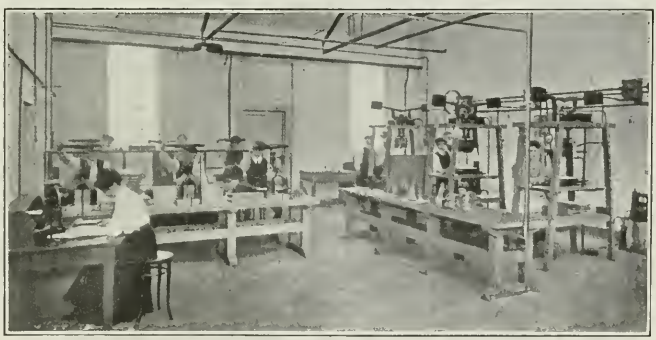

FIG. 2.—VIEW OF FILAMENT SQUIRTING SHOP.

All the binding material is driven out of the filament and only the tungsten metal remains. The entire operation is automatic after the bell has been lowered, and four filaments are treated at a time consecutively. All the operations are carried out by girls, who, of course, have no technical knowledge and do the work entirely mechanically. Further, the

quality of the product is uniformly good. This indicates the ingenuity of the automatic apparatus.

After the filaments are removed from under the forming bells they can be taken by the ends and twisted backward into a circle, a test which speaks highly for their strength and flexibility.

The forming benches occupy the bulk of the space in the filament factory; 80 girls are employed at the forming benches, each of whom can form a maximum of 600 filaments a day. At one end a number of motor-generators and air and ammonia compressors have been installed. At the other end of this department is a separate section, where the filaments are weighed and carefully cut off to standard lengths on a gauging and cutting machine. The weighing machines will register up to a tenth of a milligram.

Arrived at this point in the process of manufacture, the filaments are ready for mounting, but this work is carried on in a separate building. The lamp supports are made, the filaments are mounted in position, they are then welded in place, placed in the bulbs, and the final process of exhausting and sealing in is gone through. All these operations are carefully subdivided among the employees into groups which practically form separate departments in themselves.

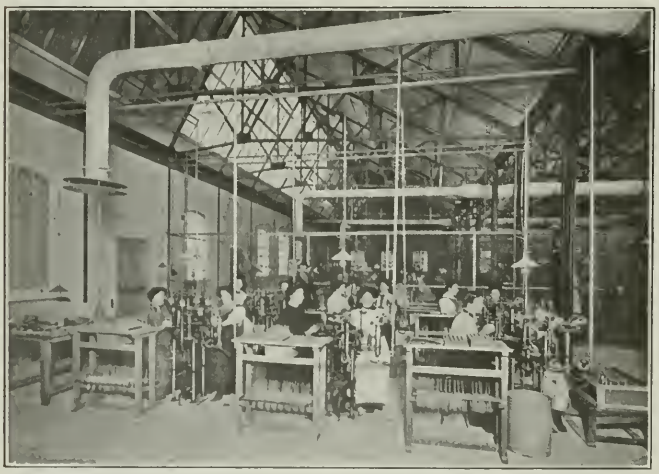

FIG. 3.—SECTION OF GLASS-BLOWING DEPARTMENT.

The foot-making, stem-making, fusing into the glass of the leading-in wires, welding of platinum tips, the fixing of the top and bottom hooks and supports for the filament, are severally delicate operations which are entrusted to each group. As the work proceeds in each department it is passed into a checking section, carefully examined and tested and passed out again, when approved, to the next section.

The leading-in wires are formed of short lengths of copper, platinum and nickel wire welded together, the platinum being a short length to pass through the glass. It is stated, however, that a new material (alloy) is being introduced in place of the platinum, which has, as platinum, the same coefficient of expansion as glass. The leading-in wires are inserted in their glass tube, which is pressed round them after being softened in a blow-pipe flame, the central glass stem is made with its circle of thin and flexible nickel hooks at the other end, and the filaments are placed in position and pasted to the lower nickel wires with a paste of finely divided tungsten paste.

The work is then checked and the filament cage goes to the welding section, where the pasted joint is electrically welded in an atmosphere of hydrogen under a glass bell. In this section the work is again checked and issued, after approval, to the sealing-in department, in which the filament cages are fused into the lamp bulb. This work is carried out on semi-automatic machines which are also attended by girls.

The final process, previous to the actual testing of the lamp, is that of exhausting and sealing off. This is carried out at special benches, each of which is fitted with a unit apparatus comprising a heating box to warm up the bulb, a number of vacuum nozzles, switches for putting the lamps in circuit, and a blow-pipe flame for sealing off.

The initial vacuum is obtained by electrically driven vacuum pumps, which are in operation in a building adjoining the lamp department and the final exhausting is carried out by Gaede rotary mercury pumps which are placed immediately adjacent to the exhausting nozzles. The outfit is the latest of its kind, and it is stated that it ensures a nearly perfect vacuum.

Manufacture of Aluminium.

In an article by Mr. Wm. Clacher in London *Electrical Review* of Jan. 20 some details are given on the manufacture of aluminium as carried out by the British Aluminium Company, Ltd. His notes on the manufacture of carbon electrodes by the same company are dealt with in a separate article in this issue.

From the molten electrolyte, consisting of alumina and its flux cryolite, there is reduction of the oxide at the point of contact of the carbon anodes, the carbon oxidizing and burning away. The metal thus produced sinks to the bottom of the electrolytic furnace, which is carbon-lined, and is drawn off thence.

This metal, from the purity of the material used—the carbon being 99 per cent and the alumina 99.9 per cent purity—is of very high percentage; over 99.5 per cent is very usual.

From the aluminium reduction works the ingot metal is taken to the mills and foundry to be worked into sheet and alloy and also for castings.

The 10-in. square carbon blocks are arranged in sets of 12 in the electric furnaces. The direct current for operating the electrolytic furnaces is obtained from 50-volt dynamos.

The plate for the bottom of the furnace is of cast iron and somewhat of the form of a grid. The interspaces are filled with carbon which is rammed and the whole plate covered. This form makes the contact between the carbon lining of the furnace and the cable much more effective.

The resistance of the carbon blocks is tested at the furnace. The carbon blocks are consumed away, the gases going to the atmosphere; hydrofluoric acid gas is also evolved from the cryolite used.

The metal as it comes from the furnace is afterward melted and the pure metal, free from any mechanical admixture, is molded in ingots. These ingots are bagged, about 20 ingots to the bag, and dispatched to the foundries and mills.

An allocation of the cost of producing the metal is given by Mr. Clacher as follows.

	Per Ton.
Energy	$25.00
Carbon	32.50
Alumina	140.00
General expenses and profit	140.00
	$337.50

This allocation of the cost seems interesting.

The power used is water-power, the most economical source of energy.

The alumina is purified from the bauxite by the Bayer process—solution in caustic soda and precipitation therefrom by addition of some previously precipitated alumina, filtered off and kilned.

The bauxite is first kilned to expel moisture, then finely pulverized; the finely divided material is mixed with caustic soda of 40 per cent strength to a fluid mass and kiered under an internal pressure of 30-60 lb. per square inch, 100 lb. steam jacketing the vessel. After eight hours the mass is blown by its internal pressure to a tank, whence the filter presses are charged; the height of the tank above the level of the presses depends on the fineness of grinding. The insoluble matter is termed red mud.

The mass when blown to the top tank is diluted to a suitable concentration and temperature, so that the wear and tear on the cloths is not heavy.

The filtered aluminate of soda is run to tanks and some alumina, previously precipitated, is added. After some time the alumina is precipitated, a white semi-flocculent substance.

This precipitate is then filtered, washed, partially dried in the press and calcined in a furnace at a cherry-red heat, after which the hard white armorphous alumina is ready for transportation in bags to the electric furnaces.

In analyzing the metal the impurities alone are determined, the difference being assessed aluminium. Of these impurities the most important are silicon, silica, sodium and iron. In practice the items customarily determined are the iron, and silica with silicon.

A New Machine for the Separation of Liquids and Solids by Centrifugal Force.

Centrifugal force is the keyword of the many inventions which have made the name of De Laval famous in the past thirty years. This is as much true for the big De Laval steam turbine which has played such an important part in the modernization of power plants as for the small De Laval cream separator which has completely revolutionized the dairying industry.

The industrial applications of centrifugal force are almost limitless, and it is no wonder that the De Laval concerns are constantly working out new machines for new purposes. In the chemical and metallurgical industries the use of centrifugal force suggests itself naturally for the separation of liquids and solids, and a small centrifugal machine of the De Laval Separator Company which is described and illustrated on page 159 of this issue, has been in successful commercial operation for some time for the clarification of liquids containing a small amount of sediment, etc.

But the bigger problem of separating liquids from solids in general (say mixtures containing from 2 per cent to 20 per cent of solids) by centrifugal force has only recently been solved. The new centrifugal separator, about which the first advance information is given in this article and which has not yet been placed on the market, is the outcome of ten years of continuous work of the engineering experts of the De Laval Separator Company, in the course of which some twenty-nine patents have been taken out for principles and details. But in view of all this, really the most surprising and most characteristic feature of the whole is the simplicity of the design.

The diagram, Fig. 1, gives a section of the machine. An outside view is given in Fig. 2, which shows a machine installed in the experimental plant. This does not represent ideal conditions, so that for continuous operation on a commercial scale some of the arrangements around the machine would be changed. The separating machine itself has so far proven equal to any task, even the most difficult, to which it has been put. Fig. 3 shows the feeding end of the machine and Fig. 4 the opposite end, with cover or cap removed, which shows the differential gear-driving mechanism. All of the moving parts of the machine are carefully encased, the only exposed part being the drive pulley, which is mounted on the shaft shown in Fig. 3.

The working or enclosed cylinder is 30 in. in diameter by 8 ft. long and revolves at a normal speed of 320 r.p.m., equal to a peripheral speed of 2513 lin. ft. per minute. Thus a product delivered into the machine is subjected to a centrifugal pressure, which causes the heavier part (the solids) to settle to the periphery.

The operation is as follows:

The raw product is delivered at *A* (Fig. 1), into a hollow arm of the supporting spider, through which it passes to the revolving cone *B*, thence to *C* and *D*. During the entering process the raw product attains practically the peripheral speed of the machine. The coarser or heavier solids are at once separated from the liquid, and by a series of broken helical scrapers, operating at a differential speed, they are drawn up an incline or cone, freed from the liquid, and discharged by the centrifugal force at *E* into the receiving chamber *F*. The liquid is discharged at the opposite end at *G* into the receiving chamber *H*.

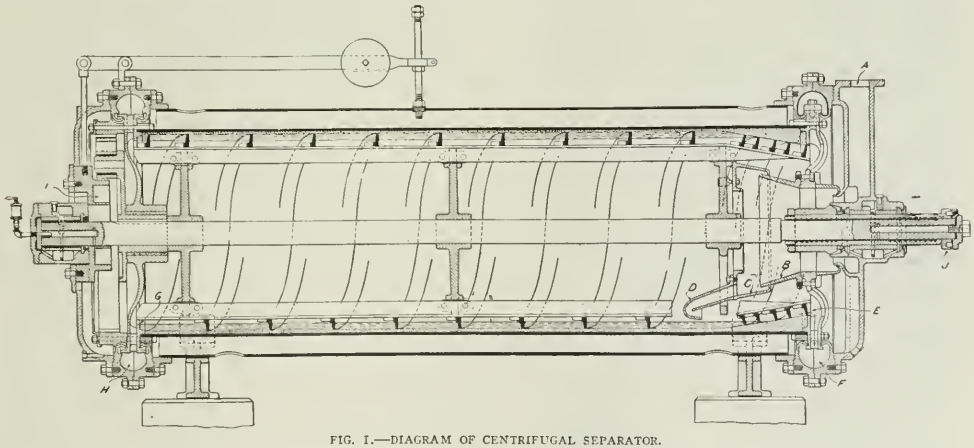

FIG. 1.—DIAGRAM OF CENTRIFUGAL SEPARATOR.

The liquid in passing to the discharge end of the cylinder travels a tortuous course, equal to 27 lin. ft. in distance, which may require one or more minutes to pass through, thus subjecting the lighter, or difficult to settle, solids to the high centrifugal pressure for a much longer period than if it was

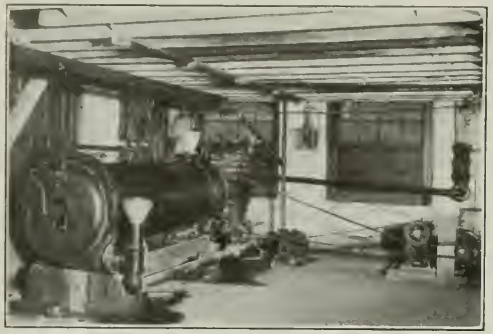

FIG. 2.—OUTSIDE VIEW OF CENTRIFUGAL SEPARATOR.

passed straight through the cylinder, the advantages and importance of which will be fully appreciated. During this period the solids are practically all settled to the periphery of the revolving cylinder, and as there accumulated from each point they are slowly drawn the length of the cylinder by the scrapers to the inlet end and discharged at *E*, as above described.

The capacity of the machine varies according to the kind of products, but unless very difficult the capacity ranges from 2400 to 3000 gal. per hour.

The speed of the machine may be varied from 150 to 350 r.p.m. to accommodate the different kinds of material.

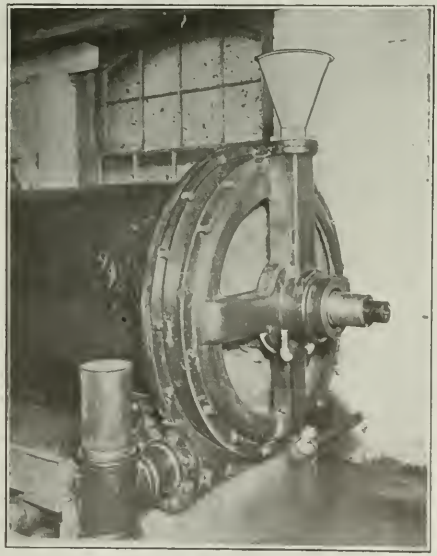

FIG. 3.—FEEDING END OF SEPARATOR.

The lever shown on the top of the machine with the round weight on end (Fig. 1) is the safety device connected to the differential driving gears and which prevents possible damage to the machine in the event of overloading or other cause. The lever is adjusted to permit of a certain pressure or force on the scrapers, and when it exceeds this amount the lever automatically rises, relieves the pressure and throws the differential driving mechanism out of commission, causing the scrapers to run in unison with the cylinder and as one piece. Without going into details, it may be said that this is one of the most ingenious details of the machine.

The machine when once adjusted to a product can be run continuously.

The weight of the machine complete is approximately 7000 lb. The oiling is largely automatic, and one man could manage and care for a number of machines.

This separator has now been working for 2½ months, for nine hours a day, in the experimental shop on a large variety of products, of which starch, sand, clay and whiting may be mentioned. Other materials are to be experimented with; thus the separator will be tried for cyanide work, etc.

From the samples of separated materials which we have seen it is safe to say that the separation obtained with this

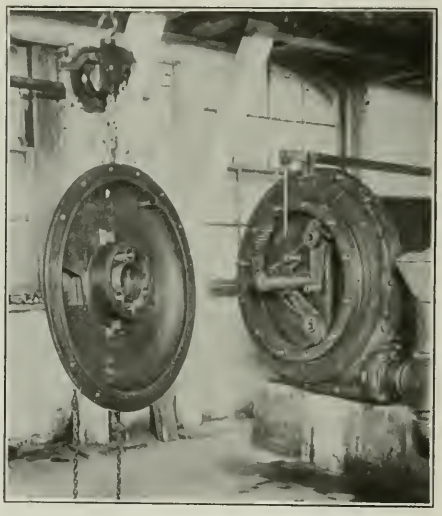

FIG. 4.—DIFFERENTIAL SPEED MECHANISM.

machine is practically perfect. If it is desired to remove the very last traces of sediment, which may have remained in the liquid discharged from the separator, this liquid may be passed through a centrifugal clarifier and filter, as described on page 159 of this issue.

Mixtures combining from 2 or 3 per cent up to 15 or 20 per cent of solids in water may be treated by this machine. The power for driving is very low. On a mixture containing 12½ per cent solids less than 5 hp is required. As mentioned before, the capacity of the machine ranges in general from 2400 to 3000 gal. per hour, according to the kind of material.

In view of the simplicity of design and practical fool-proofness of the machine, the cost of attendance and operation is very low. Its compactness and efficiency of handling quickly large amounts of difficult material should certainly attract the attention of the chemical and metallurgical engineer.

When the machine is placed on the market we expect to give further descriptions, with results of tests, though in the meantime we are sure the manufacturers will be pleased to give interested parties such further information as they may desire.

This new De Laval centrifugal separator is certainly an interesting example of the possibilities of centrifugal force and of the effectiveness of co-operation between the chemical and mechanical engineer.

Some Practical Experience with Corrosion of Metals*

By Rear-Admiral John T. Corner, C.B.

It should be pointed out at the outset that in this paper the writer purposes to limit himself to chiefly giving instances of corrosion which have come under his notice while actively engaged as a marine engineer and to detail some of the practical methods found to be efficacious in dealing with the same.

Some of the causes of corrosion of metals on shipboard are so obscure, and the origin so difficult to trace, that no satisfactory explanation is so far forthcoming. On the other hand, cases have occurred in which the causes operating to produce the effects are clearly recognized and easily dealt with.

The writer has had no personal experience of the trouble which took place through the corrosion of copper and its alloys in the old wooden ships, but that such corrosion did exist is within the knowledge of most of those who have studied the record of such ships. Cases are mentioned of copper sheathing having become corroded in mysterious ways and at unexpected times, and there are reports of the heads of the nails having corroded entirely off, allowing the sheathing to become detached.

There were doubtless at times troubles through corrosion in the bilge and other copper pipes of the old wooden steamships of war, but as a rule these appear to have been of minor importance; and in many ships the chief anxiety the engineers had concerning the pipes was to keep them in a bright and burnished condition so as to pass the captain's weekly inspection, at which the array of copper piping in the bilges was often one of the show sights of the ship.

With the introduction of iron for shipbuilding purposes the conditions are different, for it was soon found necessary to insulate as well as protect the copper pipes in or near the bilges—not, however, for their own welfare so much as for the sake of the adjacent plates and angles, which, when not so treated, were found to be adversely affected by contact, owing to the galvanic action set up between the metal pipes and the iron plating by the bilge water.

There were many instances in which very considerable trouble was caused. Among them may be mentioned the case of the troopship *Megaera*, which vessel had to be beached at St. Paul's Island about 1869 to prevent her sinking. It came out in the subsequent inquiry that among other defects in this ship there was a serious one due to a copper strainer fitted to a bilge section pipe in a remote part of the ship. The action set up by it was sufficient to eat right through the plates and so admit water to such an extent that the ship had to be run ashore to save the crew.

As far as can be ascertained the pipes themselves in iron ships were no more affected than those in wooden ships, probably not so much; and it was not until at or about the time of a great change in the internal economy of men-of-war that serious and persistent troubles through the corrosion of copper pipes began to be manifest and felt. This change was the introduction of the electric light on shipboard.

The writer's first experience of the insidious corrosion of copper pipes occurred in a ship which had recently been fitted with an electrical installation for working searchlights. During a commission of over three years there were, as far as can be remembered, only two pipes which seriously suffered from corrosion; both were water pipes, and both were eaten right through in small holes, which had the appearance of having been punched, and it is noteworthy that each of these pipes was in the immediate vicinity of an electric lead to a searchlight—the one forward and the other aft. The whole business was after all but a minor affair, and consequently very little notice was taken of it; it was only years afterward, when trying to assign a cause for similar trouble in various other ships, that the previous experience was recalled to throw light on an obscure question.

There is no doubt whatever that the time of the construction of the electric light in naval ships synchronized with a considerable increase in the corrosion of the copper and metal pipes and fittings; and as the parts affected were chiefly water fittings, the increased steam pressures which came at or near this period, and which might have been suspected as one of the causes, can be now quite absolved from any share or part of the trouble.

Sometimes pipes would be found eaten nearly, and in some quite, through in a very short period; moreover, the replaced parts often became similarly affected even when different brands or qualities of copper or brass were used. Sometimes the pipes were eaten in holes having sharp, clean-cut edges, as though punched; sometimes parts were pitted and honeycombed over a considerable area of surface; while in other examples the metal was nibbled out in such a way as almost to suggest the presence of rodents or microbes.

As regards the source of this trouble, some engineers for the reasons above stated were inclined to attribute it to electrical action due to the leakage from the mains, which was often so great as to allow electricity to permeate the whole ship. It must be admitted now that some of the earlier electrical installations on shipboard were a long way from perfect, inasmuch as leakage in some cases was sufficient to turn the ships themselves into storage batteries. Others attributed these defects in the copper pipes to induced currents set up in different parts of the ship by the currents in the electrical mains. But nothing definite could be proved, and those then dealing with the electrical plant disclaimed all responsibility for the trouble, and in fact sometimes expressed the opinion that the currents they used could hurt nothing and cause trouble to nobody.

It was also further suggested that the action might be due to mere chemical causes, but here again the responsibility for this was disclaimed by those concerned, the corrosion being put down by them to mechanical rather than chemical action; and there was certainly some ground for the contention, seeing that corrosion in pipes generally occurred at or near bends or branches; also very extensive corrosion often occurred on the bronze propeller blades, especially at the forward side where there was little likelihood of extensive action, electrical or chemical, but abundance of the mechanical kind.

It is very probable that a certain amount of chemical action was first induced by galvanic action, and the erosion caused by the friction of the water, which washed away the results of the chemical action, left the surface exposed to further and similar action. This explanation, however, would not fully apply to cases where clean-cut holes were found in the pipes, condenser tubes, etc.; these results were probably due to want of homogeneity in the composition of the metal, the galvanic and chemical action finding out the weakest places. It would also appear that the presence of air and moisture together largely influences the extent of the corrosion of these metals as of iron, and in a measure helps to explain the pitting on the forward sides of the propellor blades, where the partial vacuum formed by the motion of the screws causes air to be drawn from the surrounding sea water, which assists the corrosive action.

It was also suggested that the corrosion might be due to the use of copper of too pure a quality; and in this connection it may be noted that some locomotive engineers specify for about ½ per cent of arsenic in the copper fire-box plates, as a preventive against corrosion. So there really may have been something in this suggestion, seeing that pure electrolytic copper was beginning to be used at or about the time referred to.

But whatever may have been the causes, the pressing business of the day was to discover the cure of the complaint; the prevention of the corrosion, which affected most of the water pipes, including the condenser tubes of many ships, was what all aimed at. As regards the latter, it is understood there was

*A paper read before the (British) Institute of Metals at the January, 1911, meeting.

not much general corrosion of the tubes in iron condensers. No doubt there have been, as there still are, some instances in which the tubes of iron condensers have given considerable trouble through various causes, some of which were foul circulating water, defective materials, excessive vibration through indirect local pressure, such as the direct impinging of the steam or circulating water on the tubes, etc.; but as regards the corrosion under consideration, it may be stated generally that it is certainly much less in condensers with iron shells than in those with brass shells.

One special case of an iron condenser which came under the writer's notice was interesting and unique, and may be mentioned here: A ship with a cast-iron condenser, with circulating water outside the tubes, had been running for several years with a set of tubes which had given no trouble whatever. The ship unfortunately got ashore on a sandbank, and in getting off stirred up the sand so much as to get a large quantity deposited in the condenser on the circulating sides. On returning to port for overhaul and repairs, the tubes were taken out to get rid of the sand. This afforded the opportunity for examining and attending to the inside of the condenser shells. They were cleaned by being chipped and scraped, and finally given a good coating of red-lead paint. Shortly after the ship resumed service the condenser tubes, which up to then had given no trouble, began to go to such an extent that the chip had to be again laid up for the complete retubing of the condensers. When this was done the red-lead paint was all removed, after which no further trouble with the tube was experienced. This result clearly showed that the brass tubes were being protected when the iron shells were bare, but when covered with lead paint a corrosive action on the tubes manifested itself.

Another case of the protection afforded by iron may be mentioned: In a certain ship one particular pipe conveying circulating water was repeatedly in trouble through corrosion. This pipe would be found badly eaten away at a bend. It was taken down, patched and replaced time after time, but the corrosion still went on and continued. The chief engineer then resorted to the following expedient: He sweated a lump of copper on the outside of the pipe, so as to provide material for a screwed hole, through which a large iron bolt, about 1½ in. diameter, was fitted so that the point protruded; and no further trouble was experienced with this pipe, the bolt being screwed further in as the point became eaten away, and being entirely renewed when necessary.

These two examples appear to indicate that the presence of sufficient bare or unprotected iron in perfect metallic contact with the system strongly counteracts the corrosion of the copper or brass; the chemical or electrical or mechanical action, whichever it may be, solely or jointly, being entirely expended on the iron. It is therefore by the free use of iron or steel that it is considered the best protection of the copper or alloy pipes is provided.

Before resorting, however, to such free use of iron various other means were tried in different ships. One method was to coat the insides of the pipes with marine glue, another to use plumber's solder or tinman's solder as an internal coating. Special alloys containing aluminium were tried. Zinc slabs and blocks were used, as also zinc bars let in among the condenser tubes; and though some of these expedients effected a certain amount of good, it is considered that the present practice has more to recommend it than any of them, and that is the insertion of short iron lengths of pipe in runs of water pipes which can be easily removed and replaced; and further, the use of iron or steel doors for brass condensers with iron rods and plates in and about the tubes is very effective as a protection to the tubes and plates.

In some warships of late years the condenser barrels are made of steel. Of course in this latter case there is the possibility of a certain amount of corrosion in the condensers themselves, but as this is only to be expected on the water-side, it should not be difficult to deal with—the design of the condenser being such as to admit of the easy replacement of parts likely to be affected and provision being made for zinc protectors as in boilers.

It is considered more than probable that the reason why iron is found on the whole to be more efficient as a protective than zinc is that with the former better metallic contact is assured and maintained, and perfect metallic contact is undoubtedly an absolute necessity.

Respecting the corrosion on propeller blades, it is not known to the writer whether iron has been tried as a protection against corrosion; but he would suggest for consideration that if easily renewable plugs of iron could be put at the parts of the propeller blades where corrosion is likely to occur they might lead to a marked difference in the extent of the pitting, for it may possibly be found that so long as there is iron in the immediate vicinity sufficient to absorb the corrosive action the bronze will be entirely protected.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our Special Correspondent.)

The Corrosion of Metals and Alloys.

Mr. G. D. Bengough's lengthy preliminary report to the corrosion committee of the Institute of Metals was discussed at the annual meeting of that body on Jan. 18.

Sir William Tilden was of opinion that iron in the metallic form undoubtedly afforded protection, yet the oxide of iron, if deposited locally, was a cause of corrosion in brass tubes he had examined a quarter of a century ago; and it should be noted that ferric oxide was electronegative. There were great differences of opinion on the subject of corrosion, and it was necessary that the question should be carefully investigated. He emphasized the necessity of assimilating the conditions of the experiments to those of actual practice.

Dr. W. Rosenhain said reference had been made to the dimensions of the microstructure as affecting corrosion and there was evidence that the metal having the corrosion was more liable to pitting. If two pieces of brass were taken, one lightly strained and the second more severely strained, a coarser structure was given to the latter. It was possible that similar differences in the microstructure might result from an unequal treatment of different parts of the same tube during the drawing process.

Mr. A. E. Seaton said that brass tubes were largely used in the navy for ships' boilers 30 years ago, with iron stay-tubes, and there was not any trouble from pitting then. Condenser tubes were formerly of 16-gage thickness, but were now of 18-gage to 20-gage.

Prof. T. Turner said he had conducted some experiments on the green deposit which formed on condenser tubes. The deposit was a non-conductor and was not part of an electric cell, but that fact did not controvert the view that the green deposit might play a part in causing corrosion.

Dr. J. T. Dunn thought that pitting was the result of the presence of local impurities introduced with the water. It had been proved that local corrosion of brass was set up by small pieces of rusty iron when immersed in sea water.

Mr. Arnold Philip (Admiralty) objected that the report had been made rather from the academical than the practical standpoint. A vast amount of useful information was available from manufacturers and users on the subject of corrosion and it was a fundamental omission not to have drawn more largely on their experience. The causes of corrosion were very numerous. The chief of these were the attacks of particles of carbon, etc., hydrochloric acid in the steam, externally applied e.m.f. mechanical abrasion by steam and water, presence of air and gases at bends of tubes, thermo-chemical action, mechanical strain, intrusion of foreign matter at surface of tubes, pres-

ence of two or more phases in the alloy, character and speed of the cooling water, and impurities in the alloy.

Mr. E. L. Rhead mentioned the influence of difference in temperature on the inner and outer walls of condenser tubes as a possible cause of accelerating corrosion. The question of annealing temperatures had an important bearing on the life of the tubes. With regard to crystalline structure, manufacturers employed photographs of crystals in different sizes in order to work within specified limits. He had recently examined some steel tubes which had corroded and found that failure was due to the use of an originally porous material.

Copper-Zinc Alloys.

Another paper read at the annual meeting of the Institute of Metals was on "A New Critical Point in Copper-Zinc Alloys: Its Interpretation, and Influence on Their Properties," by Prof. H. C. H. Carpenter and Mr. C. A. Edwards.

The discussion was opened by Dr. W. Rosenhain, who, while admitting the existence of the critical point, was not able to agree with the authors in their interpretation of the facts.

Mr. G. D. Bengough was not able to coincide with Dr. Rosenhain's view, and, besides accepting the authors' theory, considered that the paper marked a distinct epoch in the history of brass. Recent researches of his own on the mechanical properties of alloys at high temperatures and on delta metal indicated that a remarkable change took place at the critical temperature, which, in his experiments, was 510° C. He also found a corresponding change in the 70:30 brass. His experiments on Muntz metal showed that at 445° C. there was not any B. constituent, which result was in accordance with the authors' conclusions.

Prof. A. K. Huntington remarked that the results of this research seemed to imply that with prolonged lapse of time all copper-zinc alloys would become brittle. He had lately made alloys with 36 per cent of zinc and less, and found that these—even after annealing—contained an appreciable proportion of the beta constituent.

Mr. E. F. Law said it was doubtful whether all inter-metallic compounds retained their identity when in solution, and this was a question which was well worth investigation. His opinion was that inter-metallic compounds were loosely combined and might behave similarly to double salts. The critical point dealt with by the authors was not a new one. Roberts-Austen recorded its existence in 1897, and, although Shepherd, Tafel and Bornemann ascribed his discovery to experimental error because they failed to detect the thermal change in question, the authors had now established beyond question that Roberts-Austen's observations were correct.

Mr. O. F. Hudson was not satisfied that the metal lost its brittleness above a certain temperature, and could subsequently revert to a brittle condition on further cooling. Brass was brittle only within a limited range of temperature. The authors' theories were consistent with the thermal observation, but not with the microscopic evidence.

Mr. E. L. Rhead said that calendering rolls, which were forced onto steel mandrils by heavy pressure, withstood a long period of work at high temperature, but after some months a longitudinal crack developed in consequence of a complete change in the character of the metal resulting from prolonged heating, and there was not much doubt that this structural change was connected with the point of inversion referred to by the authors.

Prof. T. Turner said that the establishment of this arrest point was of great consequence to brass manufacturers. It had long been known to practical men, but had never been mentioned in any text-books.

British Engineering Trade Returns.

The official statistics for 1910 published on Jan. 12 in the *Board of Trade Journal* show increases in both the imports and exports of all the principal engineering materials and manufactures. The imports of iron and steel amounted to £9,093,795, an increase compared with 1909 of £1,122,201, while the exports reached £43,002,937, a rise of £4,810,795. The imports and exports of other metals and manufactures thereof were £24,699,531 and £10,360,159, the respective increases being £353,203 and £1,651,214. The imports of electrical goods increased by £363,960 and the exports by £1,887,641, the totals for the year being £1,686,469 and £4,117,840. The imports of machinery amounted to £4,471,303, an increase of £32,967, and the exports to £29,296,721, a rise of £1,239,078. The value of ships imported was £27,104 and exports were £8,769,331, increases of £3,178 and £2,842,217. The exports of ships decreased £1,798,144 from the values in 1908.

Production of Nitric Oxide by Combustion of Hydrogen.

At high pressures the combustion of hydrogen in a mixture of equal molecular parts of oxygen and nitrogen produces a considerable yield of oxides of nitrogen. A. Walokitin states that, without heating the gases, about three molecules of nitric acid in 100 of water—approximately ten per cent nitric acid—are obtained. Pressure exerts an appreciable effect only above three atmospheres, with a maximum effect at 16 atmospheres With excess of oxygen practically the same results ensue. The yields agree with earlier results with explosion methods; but—probably in consequence of the theoretical temperature not being reached—are rather lower than the calculated values. The yield from the combustion of hydrogen in air is, of course, lower.

The Electric Furnace in Great Britain.

The *Times* of Nov. 30 calls attention to the reluctance of British steel manufacturers to advance with the times in the matter of electric furnaces. The article says that to England, with a rapidly diminishing stock of high-grade ore, the electric furnace is of peculiar value, as offering a means by which high-class steel can be manufactured from such low-grade ores as those from Cleveland, Lincolnshire and Northamptonshire; and proceeds to combat the argument that the absence of water-power is a fatal impediment to the extensive adoption of the electric furnace in England. The writer points out, too, that in the great manufacturing centers waste gases from blast furnaces and coke ovens as well as exhaust steam furnish sources of power which could be utilized for electric steel refining; and, further, that it is believed that there is at least one English manufactory which is buying electric energy at ⅛d per unit. This is an exceptional case, but indicates future possibilities. The article referred to is inspired by the adoption of the Heroult patents by the United States Steel Corporation

The Cost of Electric Energy in England.

An editorial note in the Engineering Supplement of *The Times* of Nov. 30 pointed out the misapprehension existing with regard to especial cheapness of electric energy obtained from water-power abroad as compared with the rates at which current can be supplied in England. In *The Times* of Dec. 7 Mr. A. S. Esslemont stated that he had recently made a tour of Norway, Sweden and southern Europe to study this question and found the average price of electric energy from water-power no lower than can be obtained to-day, for similar loads, from the power companies on the northeast coast of England. He pointed out that the very low prices often mentioned as being prevalent in Norway and Sweden are frequently misleading, the prices varying from $6.25 to $8.75 per electric hp-year. He stated that the Hydroelectric Power Company does not offer such terms; they are quite exceptional and are only occasionally obtainable under especially favorable circumstances. He considers that steel works on the northeast coast are in a better position to adopt the electric furnace so far as a supply of electric energy is concerned than many of their continental competitors, by reason of the huge output of the supply companies and their policy and enterprise in utilizing the waste gases from blast furnaces and coke ovens.

The Physical Society's Exhibition.

The Physical Society's sixth annual exhibition was held at

the Imperial College of Science and Technology on Dec. 20. The exhibits included almost all the newest and best forms of scientific apparatus from some 35 of the leading firms in Britain; and there was a very good attendance. Even to name all the various apparatus well deserving of commendation would extend this notice to an inordinate length, and only those more directly of interest to engineers will be mentioned. The Cambridge Scientific Instrument Company showed Peake's patent compensating leads for thermo-couples, the Brearley recalescence curve tracer, and a new "Bi-meter" CO_2 recorder, which consists of two meters with an intermediate absorption chamber; Messrs. A. C. Cossor had Rose's high-vacuum oil pump, suited to the exhaustion of lamps; Messrs. Crompton & Company pyrometers, thermo-couples and electrical instruments; Messrs. Elliott Brothers, micrometer gages and the Wimperis accelerometer; Messrs. Everett, Edgcumbe & Company photometers and the Trotter combined accelerometer and gradient measurer; Messrs. Evershed & Vignoles, the Digby & Biggs "Dionic water tester" by which, from the conductivity, the degree of hardness, amount of condenser leakage, priming and sewage pollution may be rapidly determined; the Foster Instrument Company, a fixed-focus radiation pyrometer giving direct-temperature readings without focussing or other adjustment, and a base metal thermo-couple of high e.m.f. and low resistance; Messrs. Gallenkamp & Company, an electric furnace designed for experiments in recalescence and radiant heat; Messrs. J. J. Griffin & Sons, improved electric furnaces; the India Rubber, Gutta Percha & Telegraph Works Company, the Bleeck-Love primary battery—a new two-fluid cell giving 2.7 volts with great current capacity and constancy; Messrs. Muirhead & Company, an electromagnetic rectifier which utilizes all the wave and has an efficiency of about 90 per cent; Mr. R. W. Paul, new patterns of thermo-electric and resistance pyrometers and a thermo-electric indicator which can be read from a distance of 20 ft. to 30 ft.; Messrs. Reynolds & Branson, a lamp for testing color-vision; Messrs. Townson & Mercer, the Wanner optical pyrometer, and Somerville's CS_2 and H_2S apparatus for gas testing. The optical apparatus shown by Messrs. R. & J. Beck, Messrs. J. H. Dallmeyer & Company, Messrs. A. Hilger, Messrs. Newton & Company and Messrs. Carl Zeiss was of a very high standard.

New Process of Extraction of Copper and Zinc from Complex Ores.

Dr. W. Hommel and Mr. H. T. Durant subject a mixture of roasted ore and water to the action of cooled sulphurous acid gas, obtained from an ore-roasting furnace. The sulphite solution thus formed is collected and submitted to the action of hot gases containing sulphurous acid from the roasting furnace, the excess of sulphurous acid being thereby driven off to enrich the escaping furnace gases, and the copper or zinc is precipitated as monosulphite. The process has been patented.

A New Scotch Iron Ore Field.

The iron ore recently discovered in the Island of Raasay is of rather low grade, only about 30 per cent, but is quite fit for making foundry iron. The island has an area of 28 sq. miles and there is an excellent site for the construction of a harbor. After the field has been thoroughly proved, Messrs. William Baird & Company propose to erect blast furnaces to smelt the ore on the island and to take the necessary coal from Clyde ports by steamers, which will return laden with pig iron.

Corrosion of Copper and Iron Alloys by Aerated Salt Water

A piece of "delta" metal corroded by sea water was found by Mr. W. P. Jorissen to contain 41.1 per cent of cuprous oxide, no cupric oxide and no zinc. Cuprous oxide was also formed by the action on copper of sea water or sodium chloride solution of similar strength for two years. If copper is partly immersed in distilled water cuprous oxide is produced on the parts submerged and cupric oxide on the surface exposed to the air.

Samples of iron, some corroded underground and some by sea water, contained both ferrous and ferric oxides and from 14 per cent to 45 per cent of substances insoluble in hydrochloric acid and which contained 50 per cent and upward of carbon. This, together with the fact that the specific gravity of the samples varied from 2.0 to 2.53, shows that a large proportion of the iron had been dissolved.

Preparation of Tantalum Compounds from West Australian Fergusonite.

A specimen of fergusonite from West Australia was found by Messrs. E. Wedekind and W. Maas to contain 54.22 per cent of Ta_2O_5, 27.73 per cent Y_2O_3, 1.8 per cent Cb_2O_5, 3.2 per cent Ce_2O_3, and 0.36 per cent ThO_2. After separation of the basic and acid constituents by the Krüss and Nilson method (Abtr. Chem. Soc., 1887, 706), the residue consisted essentially of tantalic, columbic and titanic acids; 7.5 gm of the residue were carefully added to 15 gm of fused sodic carbonate in a platinum crucible, than a further addition of 4 gm of sodic carbonate and 1.6 gm of sodic nitrate was made; after cooling the fused material was extracted with 750 cc cold water, filtered and left till next day, when 6.4 gm of sodic tantalate had crystallized out. The best crystals were removed, the rest was dissolved in much hot water, and, after cooling, tantalic acid was precipitated by carbon dioxide, dried at 100° C., treated with a little fuming nitric acid, evaporated to dryness, and ignited to pentoxide.

Market Prices.

January, 1911.

Copper has shown, on the whole, a downward tendency. Starting at £56.10.0 it had fallen by the 13th to £55.6.0, recovering sharply to £56.2.6 on the 18th, afterwards sagging and closing at £55.50.

Tin has made a very strong upward movement on the whole month. Opened at £179.18.0, and rose in three sharp jerks followed by equally sharp depressions to £185 on the 10th and £190.10.0 on the 18th. It has since been to £192.10.0, but closes at £190.

Lead has been steady with slight downward tendency. Opened at £13.10.0, closed at £13.7.6.

Hematite has been irregular. Opening at 66/6 it rose to 67/- by the 9th, and remained fairly steady till the 17th, afterward dropping suddenly to 66/-, and then rising with irregular movements to 67/2½.

Alum, lump, loose	£5	12	6
Antimony, black sulphite powder, per ton	22	0	0
Borax, British refined crystal, per ton	16	0	0
Sal ammoniac, lump, first delivered U. K., per ton	42	0	0
Copper sulphate, per ton	19	5	0
Caustic soda, ash, 48 per cent, ordinary, per ton	5	10	0
Litharge, flake, per ton	15	10	0
Sulphur, recovered, per ton	5	0	0
Camphor, 1-oz. tablets		1	7
Shellac, standard T. N. orange spots, per cwt.	4	4	0
Hydrochloric acid, per cwt.		5	0
Copper ores, 10 to 25 per cent unit.	8/10½ to	9	10½
Tin ore, 70 per cent, per ton	£116 to £118		
Carbolic acid, liquid, 97/99 per cent, per gal.		1	0
Creosote, ordinary good liquid, per gal.			2
Naphtha, solvent, 90 per cent at 160° C., per gal.			9
Mica, small slab, original cases, per pound	6d to	1	0
India rubber, Para fine, kept in the neighborhood of 5/4 till the 11th, afterwards falling to 4/10, thence recovered sharply, closing at		5	3
Platinum, per oz.	8	0	0
Sulphate of ammonia, f.o.b. Liverpool, per ton	13	7	6

The most marked advance (excluding tin ore) is that of sulphate of ammonia, 10/9 per ton. Copper sulphate is down 5/-, litharge 5/- dearer, sulphur 5/- dearer, shellac up 1/-, copper ore down 6d, tin ore up £12, naphtha solvent 1d less per gallon, and india rubber 1/- cheaper.

Of the metals tin and iron have improved, copper and lead are slightly down.

Synopsis of Metallurgical and Chemical Literature

Iron and Steel.

Tests of Metals by Alternate Stresses.—A. Boudouard has made tests on the influence of alternate stresses on various metals, and has summed up the results in a paper in the *Bulletin de la Société d'Encouragement* of December, 1910. A metal can be fractured, not only by applying once a breaking load, but also by submitting it to often-repeated tensions and compressions of much smaller magnitude. The resistance of metals to alternate stresses is of great importance in industrial application of steels. A metal is not perfectly elastic, and when an effort which has caused a deformation disappears the piece returns approximately to its initial form, but, nevertheless, it suffers a permanent deformation, though a very feeble one. This residual deformation is negligible compared with the elastic deformations, but very frequent repetitions can produce a profound change of the metal, and even a fracture. The first steel examined in these tests was a good commercial steel with 0.3 per cent carbon, first in its natural state, then, after having been annealed at 350° for 10 hours without access of air, and finally hardened by water quenching from 1000° C. The bar of the steel in its natural state broke after 12½ hours continued vibration, or 1,350,000 vibrations. The annealed bar broke after 4½ hours and 486,000 vibrations. The hardened bar broke after 30 minutes, and 54,000 vibrations. The rupture always took place near the spot where the steel bar was clamped, called here the clamping place. The coming rupture indicated itself in advance by a dampening of the vibrations. At the moment of breaking the free part did not fall off at once, but could only be separated from the other part by some effort. Examination of the section with the naked eye showed parallel zones with grains of different sizes, indicating the phenomenon of shearing. Following are the results of the tests with different metals:

1. *Puddled Iron.*—Iron studied in the natural state; annealed at 950° C. and cooled in air. Bar broke after 18 hours 45 minutes, or 1,995,000 vibrations. The break occurred 5 millimeters inside of clamping place, and pieces were separated with great difficulty.

2. *Very soft steel,* annealed at 950°, cooled in air. Bar broke after 11 hours 15 minutes, or 1,215,000 vibrations. Break occurred 7 millimeters inside of clamping place, and pieces were separated with great difficulty.

3. *Steel with* 0.3 *per cent Carbon.*—Studied first in the natural state (annealed at 900°, cooled in air), and, secondly, hardened (heated to 900° C. and quenched in 15° water). The steel in its natural state broke after 13 hours 15 minutes, or 1,431,000 vibrations. Break started several millimeters inside of clamping place. When drawn out of vice jaws, bar remained in one piece and was only separated with great difficulty. Fracture seemed to extend from the interior to the exterior. The hardened steel bar broke after 14 hours, or 1,512,000 vibrations. Fracture began 12 millimeters outside of clamping place. The sections showed results of shearing of metal particles.

4. *Steel with* 0.6 *per cent Carbon.*—Studied first in natural state (annealed at 850°, then at 700°, and cooled in air), and secondly, hardened (quenched from 850° in 15° water). Annealed bar broke after 6 hours, and 648,000 vibrations. Fracture showed 2-3 millimeter outside of clamping place, and the same observations as on 0.3 per cent carbon were made. The hardened bar broke after 1 hour 55 minutes, and 153,000 vibrations. Fracture started several millimeters inside of clamping place. The two sections of the bar separated without much effort. Sections showed results of shearing. Fracture is not perpendicular to longitudinal axis of bar, and found to be very irregular.

5. *Steel with* 1 *per cent Carbon.*—First in natural state (annealed at 850°, then at 650°, and cooled in air); second, hardened (heated to 850° C. and quenched in 15° water); third, heated to 850°, quenched in 15° oil bath, and reheated to 350° without access of air. The natural steel bar broke after 3 hours 55 minutes, and 369,000 vibrations. Fracture was produced several millimeters outside of clamping place, and same phenomena as in natural steel of 0.3 and 0.6 per cent carbon were observed. The hardened bar broke after 5 minutes, and 9000 vibrations, 7-8 millimeter outside of clamping place. This was due, however, to fracture of the bar during mounting for test. The hardened and reheated bar did not break after 26½ hours, and 2,862,000 vibrations. Tests were not continued on this bar.

The general conclusions are summed up as follows: As these tests can be repeated under same conditions several times, they can be used to find the resistance of steels to alternate stresses. Sufficiently prolonged vibrations lead to the ultimate breaking of the metal. The number of vibrations necessary for breaking varies inversely as the carbon percentage of the semi-hard and hard steels. Puddled iron and very soft steels with similar chemical composition, except for manganese, which varies between 0.050 and 0.400 per cent, present a much greater difference from point of view of length of time for vibrations to produce fracture. The puddled iron has a much greater resistance than the soft steel; 0.3 per cent carbon steel, annealed or hardened, shows no appreciable difference. In the case of hard steels hardening decreases the length of time necessary to produce break considerably. Reheating improves the metal, shown by the last case, where a 1 per cent carbon steel did not break after 26½ hours' vibrations, when reheated.

Examination of the fractured sections shows similarity. Lines of separation, along which the fracture gradually takes place, can be seen. The size of the grain varies in the different zones, and appears notably enlarged in hardened steels. Shearing lines are seen perpendicular to the edges of the fractured section. As regards the mechanical properties, the high elastic limit of puddled iron and very soft steel is pointed out, after having been subjected to vibrations leading to break. All the metals tested broke, although tested considerably below the elastic limit. Some observations were also made on the dampening of the vibrations just before metal breaks.

Gold and Silver.

Improved Grinding Pan Discharge.—In the *Monthly Journal* of the Chamber of Mines of Western Australia, Mr. G. C. Klug describes a simple expedient for obtaining a uniform discharge from grinding pans. The design is by C. C. Freeman, who introduced it at the Great Fingal mill, where it has been in successful use for over a year. It consists of a curved 3-in. pipe introduced into the side of a Wheeler 5-ft. pan opposite the feed and about 12.5 in. below the top. As the mullers revolve at 60 r.p.m. the only product which can flow out of the pipe is the —30 mesh, this being sufficiently light to be unaffected by the centrifugal force produced by the revolution of the mullers. This classifying action of centrifugal force is remarkably effective, as the overflow contains only 4 per cent to 6 per cent of coarse material, as against 10 per cent to 15 per cent which formerly was mixed with the —30 mesh when ordinary classifiers were used. The stamp battery product which goes to these Wheeler pans is crushed through a screen having seven holes per linear inch. One pan will take care of the output of five stamps. The stamp duty has been increased from 7.5 tons to 9.2 tons per day as a result of the change.

Revolving Pressure Filter.—A horizontal tubular revolving filter is an innovation installed at El Oro mill, Mexico, where six units are in operation, handling 1000 tons of slime per day at a cost of about 4 cents per ton. The filter is the invention of EDWIN BURT, who describes it in the Jan. 21, 1911, issue of the *Engineering and Mining Journal*. Each filter consists of a cylinder 42 in. in diameter and 40 ft. long, set in a horizontal position. The head end is closed with a casting bolted to the flanges of the shell. The discharge end is closed by a plate operated by a hydraulic cylinder and piston, working under 125 lb. pressure. The filter revolves on trunnion bearings at the head end, and on roller bearings near the discharge.

The inside of the filter is lined with 20 filter cloths, each 26 in. by 10 ft., placed with the long axis corresponding to that of the tube. This allows five cloths to the circle and 10 to the length of the tube. The cloths are held in place by curved angle irons, staggered throughout the interior in such a way that they act as a spiral guide for the discharge of the cake when it is washed. Midway in the length of each cloth is a nipple and screen inserted through the shell of the filter for the discharge of the filtered solution. As there are five cloths in the circle there are five nipple discharges in the circumference of the tube at four points in its length. Each filter cloth is a unit in itself and its discharge may be plugged independently of the others if the effluent is cloudy.

A set of five valves at the head of the filter is used in the manipulation, viz., one 4-in. slime feed, one 2-in. wash solution, one 2-in. wash water, one ¾-in. compressed air and one 3-in. escape for reducing pressure. The filters revolve continuously. When the doors are closed the slime feed is admitted, under a gravity head of 60 ft., until the gage shows 35 lb. pressure. The feed is then closed and compressed air passed in to bring the pressure up to 40 lb. This is maintained until the solids are caked. Wash solution is then introduced and the same procedure followed. Finally wash water is used in the same way. The pressure is then dropped to zero, the discharge door opened and the cake discharged by the action of the curved angle irons after it has fallen from the walls of the tube. An acid bath is given once a month to remove lime salts. The life of the cloths is about four months; cost of renewal, less than 0.4 cents per ton of slime filtered. Time required for complete cycle: Charging slime, 3 minutes; making cake, 23 minutes; washing, 33 minutes; discharging, 3 minutes; total, 62 minutes.

Copper.

Purification of Electrolytes.—Writing in the *Australian Mining Standard* for Dec. 28, 1910, and Jan. 4, 1911, Mr. H. SCHRODER describes work done at Lithgow, N. S. W., on the purification of electrolytes used in electrolytic copper refining.

Crystallization Method.—The old method used was to draw off a portion of the electrolyte each day into lead-lined evaporating tanks having a hard lead coil in the bottom, connected with exhaust steam from the engines. The solution was evaporated to sp. gr. 1.4. The evaporation amounted to about 3 in. of solution every 12 hours from a tank having a surface area of 7 ft. 6 in. x 3 ft. 6 in. While still hot the solution was syphoned into crystallizing tanks in which were suspended strips of lead on which the copper sulphate crystallized. When the solution had cooled the strips were removed and the crystals detached. The solution was then reconcentrated and recrystallized, but a third crystallization could not be advantageously effected on account of the impurity of the crystals obtained. Consequently, the impure mother liquor was passed over scrap iron contained in boxes similar to zinc boxes used in gold precipitation and the remaining copper recovered in this way. The hot mother liquor solution was delivered to the scrap-iron boxes at the rate of 2 gal. per minute and issued from the fifth box free from copper. The waste liquor, being a strong solution of iron sulphate, was discarded. Much sulphuric acid was lost by this method which might have been saved by first saturating the solution with scrap copper. This, however, would have added to the production of bluestone, and as there was only a limited market for this the plan was not adopted.

The cement copper obtained from the scrap-iron boxes was dried and roasted and gradually worked up by charging it in small lots into the refinery with pigs of rough copper. But the elimination of arsenic was not great and eventually most of it got back into the copper anodes by way of flue dust subsequently collected and melted. Roasting the cement copper by itself was ineffective for the removal of the arsenic, for although dense white fumes came off there was less than 30 per cent arsenic driven off.

The entire method could have been improved by first saturating the solution with copper, making three batches of crystals and thereby reducing the amount of impure cement copper to be dealt with later. This latter might have been stored, mixed with flue dust or fine ore and smelted to a rich matte which could have been blown to blister and thus eliminate most of the arsenic; for while mere roasting of the cement copper is ineffectual in removing arsenic, still the reverberatory smelting and converting will remove it to a great degree, as has been shown by authorities on copper smelting.

Experiments with Insoluble Anodes.—These were instigated by G. H. Blakemore, and although never completed, owing to the works being closed, enough data were obtained to show the nature and results of the work. The object was to purify the electrolyte and at the same time produce the least quantity of impure copper. First a portion of the ordinary electrolyte in circulation was shunted off and circulated through a series of tanks fitted with lead anodes to reduce the copper content. The flow was regulated so that the solution leaving the last tank still contained enough copper to precipitate pure metal.

This liquor then flowed into a second set of tanks provided with insoluble anodes and circulation stopped. The current was then applied and in 8 to 12 days all the arsenic and bismuth were deposited. The cathodes were perfectly black and a large portion of the deposit fell to the bottom of the tank. The solution still carried about 2 per cent $CuSO_4 . 5 H_2O$, and was about 50 per cent stronger in sulphuric acid than the regular electrolyte. In one experiment the electrolyte contained 10 per cent $CuSO_4 . 5 H_2O$. After three days the $CuSO_4 . 5 H_2O$ was reduced to 2.08 per cent and remained at that for four days more, by which time all the bismuth was removed and the arsenic reduced to a very small amount. The current density was 7 amp per square foot of cathode surface and the drop across each tank was 2.20 volts.

With a view to reducing the quantity of impure copper produced in the non-circulating tanks an experiment was run to determine how far the copper content of the ordinary electrolyte could be reduced without impurities being deposited. It was found that 7 per cent $CuSO_4 . 5 H_2O$ was about the limit of safety, as below that figure the impurities would precipitate with the copper.

The author draws the following conclusions from the experiments: (1) Using a current density of 7 amp per square foot of cathode surface at 7 per cent $CuSO_4 . 5 H_2O$ and up to 14 per cent free H_2SO_4 (starting with 13 per cent copper sulphate and 12 per cent free acid) the cathodes darken and bismuth and arsenic begin to deposit. On two occasions, when circulation stopped during the night, it was found that at 8 per cent copper sulphate the cathodes were bright, at 7 per cent dull and at 5.5 per cent quite black. (2) Using the same current density in a non-circulating solution with insoluble anodes arsenic was removed at a regular pace. Starting with 0.54 g. As_2O_3 per liter it required 12 days to lower it to 0.15 g., whereas most of the bismuth was removed in the first two days and the copper sulphate never got below 2 per cent. With 14 amp the solution was reduced to 1.7 per cent copper sulphate and the arsenic to 0.015 g. in six days.

The suggestions offered are that the copper content of the

electrolyte be reduced in lead anode tanks to the safety mark before treatment in non-circulating tanks. The whole of the impurities would then be concentrated in a small amount of copper which could be roasted with a small amount of matte and blown to blister separately, thus eliminating the arsenic to a large degree. Or the impure copper could be melted and treated as anodes in a separate tank and the cathodes, so produced, removed as long as they remained pure. The resultant solution could be concentrated and crystallized as long as pure crystals were obtainable, and the mother liquor either discarded or precipitated on scrap iron and the cement copper rich in impurities disposed of to the best advantage. In any case it would be better to discard a small quantity of copper than to return the impurities to the tank house.

Occluded Gases in the Alloys of Copper.—Messrs G. Guillemin and Delachanal have made extensive studies of the occluded gases in copper alloys, and they report on the results of their investigations in the *Revue de Metallurgie* of January, 1911, as follows:

Tin, phosphor-bronzes and brass, as used in the industries and naval construction, were tested for occluded gases. For these tests quartz tubes were used, as the porcelain tubes were found to be too fragile. The opaque quartz tubes were first tested as to their impermeability to gases, both at a temperature of 1100° C. and in the cold state. In the cold they were impermeable. They were then kept under a vacuum at 1100° for ten hours, and only very slight quantities of gas were evolved, consisting of carbon dioxide and some traces of organic matter, which had entered the tubes in spite of all precautions. The error due to this is, however, so slight that it is negligible. The conclusions derived from the test are as follows: Special forgeable brasses retain important volumes of occuluded gases (1 to 30 vol.) composed of hydrogen, carbon dioxide and carbon monoxide. In sound samples the of occluded gases (1 to 30 vol.) composed of hydrogen, carhydrogen. In unsound cast samples the hydrogen is accompanied by a considerable portion of carbon monoxide and a little carbon dioxide. In sound pieces the presence of occluded hydrogen, even in considerable proportions, seems to have no bad influence on the mechanical properties of brasses which can be forged. Phosphor-bronzes have very little occluded gas; this is composed entirely of carbon dioxide and hydrogen. (As in the case of cast iron and steel, phosphorus seems, therefore, to diminish the solubility of hydrogen in the metal.) The occluded gases can only be extracted by employing an increased temperature and at least a partial volume. The article gives a complete table showing the composition of the pieces tested, the volume of gas extracted, composition of the gases, which were CO_2, H, CH, CO, and some of the rare gases, like argon, etc.

Zinc.

Recovery of Zinc in Liquid State Direct from Zinc Blende.—F. Thomas, in *Metallurgie* of Nov. 22, 1910, reports on the results of tests made for the purpose of obtaining zinc in liquid state direct from blende by electrolysis. A very fusible silicate mixture whose melting point is below the boiling point of zinc, 920°, was first thought of, and for this purpose silicates of Mn, Al, Mg, Ca, Sr, Ba, Na, K were picked out. The curve of the melting points of mixtures of Na_4SiO_4 and K_4SiO_4 shows a minimum (743° C.) for 50 per cent Na_4SiO_4 and 50 per cent K_4SiO_4. The further addition of 6 per cent manganese silicate reduced the melting point to 700°. The solubility of ZnS in this silicate mixture was tested up to 1000°. At 900°, the maximum temperature which can be used lest zinc is lost by evaporation, only 0.5 per cent zinc sulphide is dissolved in the silicate mixture. Electrolysis of ZnS in this silicate mixture was then tried in two furnaces of Borchers. The result of all the tests was the same, namely, a fine distribution of zinc globules throughout the mass and a separation of a very small regulus in two tests only. The probable reasons for failure are the formation of a collodial zinc dust from the cathode and the slow speed of solution of ZnS in the silicate mixture at temperatures below 900° C. Electrolysis under pressure was then tried in order to employ higher temperatures, and in this way 52.6 and 67 per cent zinc were recovered, although mostly in form of zinc dust. However, these tests were given up as not promising success. Further tests were then made, trying a solution of ZnS in a Na_2S—FeS mixture. The intended reactions were $Fe_2O_3 + 2\ Na_2SO_4 + 11\ C = 2\ (Fe + Na_2S) + 11\ CO$ and $Fe + Na_2S + ZnS = (FeS + Na_2S) + Zn$. Fe_2O_3 and Na_2SO_4 were reduced at 1100°. Fifty grams of the reduced mixture were mixed with 36.15 grams ZnS and heated at a constant temperature for a long time. At temperatures below 920°-960° a precipitation of zinc by iron dirt did not take place. Tests in which the fusibility was increased by adding $CaFe_2$, and the intention was to increase the speed of reaction by an increase of the Fe content, had a negative success.

Tests were then made to separate zinc under pressure at higher temperatures. The zinc deposited on the cover of the crucible in form of dust. In one test, which lasted 30 minutes and in which the pressure was 2-3 atmospheres, 55 per cent zinc was recovered as dust. The reaction between the Fe and S takes place near the highly heated carbon resistor, and the Zn rises as vapor upward along the carbon resistor, which is probably so hot that at its temperature the partial pressure of the zinc vapor is higher than the pressure in the electric furnace. The vapor rises, therefore, to the surface and condenses on the relatively cool walls of the iron crucible and crucible cover in form of dust.

The last tests were made with electrolysis of ZnS solution in a fused sodium sulphide-iron sulphide mixture, using Fe-anodes. The greatest percentage of metal recovered was 14.7 per cent; there was again the formation of a zinc mist or fog, which extended from the cathode. Although the results are negative, the paper is interesting.

Assaying.

A Portable Assay Outfit for Field Work.—Engineers who have had occasion to prospect in isolated regions where assay offices are few and far between will be interested in a contribution to the January, 1911, *Bulletin* of the Amer. Inst. of Min. Eng. by S. K. Bradford. He gives full details of equipment and procedure and shows the ingenuity which can be exercised when ordinary laboratory facilities are not at hand. The equipment is packed in an ordinary 26-in. valise and suffices for about 100 assays of commercial accuracy.

Equipment.—Small hammer; steel mortar with stand sawed off flat to serve as an anvil; small steel pestle; blow pipe and blow-pipe cupel holder; small and large spatulas; button pliers; light 1-in. cupel mold; two 3.5-in. x 8-in. muffles; 18 "F" crucibles; six crucible covers; crucible tongs; 25-cc. burette; six 0.5-oz. parting flasks; six 0.5-oz. annealing cups; two or three beakers; hand balance, folding in a tin box; set of gram weights; one 6-in., 60-mesh screen; six small glass stirring rods; teaspoon and tablespoon; a micrometer for measuring diameter of buttons. The latter may be a short fixed microscope stand in which has been placed a scale of 0.1 mm—two or three extra object glasses being carried for safety. Chemical reagents in bottles in metal containers: 0.5 lb. KCN; 1 lb. C.P. HNO_3; 1 lb. C.P. HCl and 2 lb. aqua ammonia. A few ounces of sheet copper; 1 oz. C.P. sheet silver; 0.5 lb sheet lead; 2 lb. tenpenny wire nails; 5 lb. bone ash; 5 lb. sodium bicarbonate; 5 lb. litharge; 3 lb. red lead; prepared charcoal for blow-pipe use; candles and old newspapers.

It will be possible to obtain sodium bicarbonate at country stores and bone ash may, on occasion, be made in the field. Sheet lead may be made from bullets and silver can be obtained from coins of known fineness.

The assays can be fused in a blacksmith's forge, which is to be found at every mining camp, and the cupelling can be done at the same place by setting up the small muffle mentioned. The weight of the buttons obtained can be determined by meas-

uring them and referring to a previously prepared scale based on specific gravity multiplied by solid contents. This method of determining weights can be found in the *Transactions* of the A. I. M. E., xxxi, 800 (1901).

Recent Metallurgical Patents.

Gold and Silver.

Treatment of Auriferous Sand.—A process for treating black sand, concentrate and the like has been patented by Carl F. Siegert, of Jeppes, near Johannesburg, Transvaal. The invention consists in roasting the refractory material, or heating it to a dull red heat, and quenching it in a solution of sodium and ammonium chlorides to free the gold from oxides. The solution is then evaporated and sulphuric acid added to the comparatively dry mass. Water is subsequently added and the mass mixed. After the dilute acid has remained in contact with the ore for a suitable time it is drawn off and the mass is washed with water. It is claimed that this treatment will render the precious metal content free for recovery by amalgamation in the usual manner.

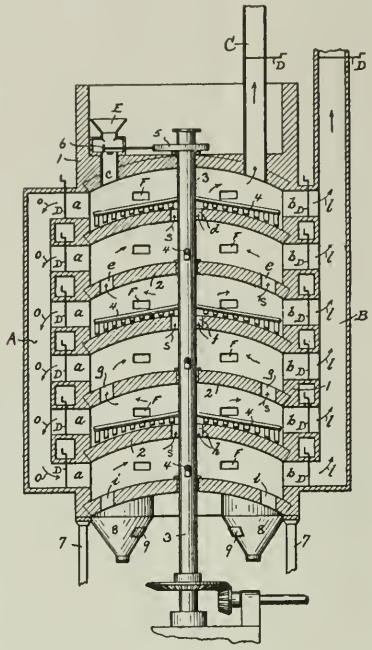
For each ton of material the inventor uses about 42 gal. of water and 10 lb. NaCl, to which is added 2 gal. of strong salammoniac solution made by dissolving 2.5 lb. to 3 lb. salammoniac in 100 gal. of water. This solution is used for the first treatment. For the acid wash he uses 1 lb. of sulphuric acid, more or less, as needed, and adds water after the acid has been poured on the mass. (981,696, Jan. 17, 1911.)

Roasting.

Improved Roasting Process.—For the purpose of improving the quality of gases produced in roasting sulphide ores for the manufacture of sulphuric acid, Charles W. Renwick, of Isabella, Tenn., has patented a furnace of novel construction. In the usual roasting furnace the ore is fed at the top and passes downward over a series of hearths to a discharge beneath, and the air is admitted at the bottom and rises through the several hearths to a stack at the top. Metallic sulphides are thus roasted to oxides and as they are catalytic agents they convert SO_2 into SO_3 in quantities varying with the conditions. In the ordinary procedure described the inventor says that the most limited catalysis is produced. It is his object to reverse the current of gases and cause them to flow down with the ore in order to carry the high temperature found in the upper hearths down to the lower for the better roasting of the ore and in order to have the SO_2 come into more frequent contact with the metallic oxides so that more SO_3 will be formed .

The accompanying drawing, Fig. 1, illustrates his preferred form of apparatus. It consists of an ordinary furnace shell with two vertical flues on opposite sides, one for drawing off all or a part of the gases from any of the upper hearths and entering them into the lower, and one for drawing off all or part of the gases, depending on the amount of conversion desired, and conducting them to the place of use.

In addition to the usual construction of the type of furnace shown, the points of which are generally understood, the improved type embodies flues *A* and *B* placed at opposite sides of the furnace body and having branches *a, b*, provided with dampers *D* which communicate through openings in the furnace shell with the several hearths, so that when the damper *D* in the stack *C* is closed, and the doors *F* properly opened for the admission of air the gases can be taken from any of the upper hearths and directed into those below and passed into the flue *B;* or they can circulate up in the ordinary way after subjecting the desired quantity of SO_2 to catalytic action, the damper in the stack *C* being opened for this purpose. By closing the dampered openings and all the dampers *D* except the one in the lowermost branch flue *b*, the entire draft in the furnace will be downward and through the openings *d, e, f, g, h*, and upward through the flue *B*, air being admitted at the top. All or a part of the gases can be taken from any of the hearths and turned down through flue *A* to any of the lower hearths and carried over to flue *B*, the dampers *D* being open in the branch flues *a, b*, at the point where it is desired that the gases shall pass out of certain of the hearths and into certain of the others and thence on to flue *B* or stack *C* as desired.



ROASTING FURNACE

The inventor further claims that the reversal of the gases will increase the temperature of the gases on the lower hearths and thus break up all sulphates and give a sweet roast, in addition to increasing the conversion of SO_2 to SO_3. (981,880, Jan. 17, 1911.)

Alloys.

Magnesium-Zinc Alloy.—The development of the aeroplane and airship has introduced a demand for light and strong metals or alloys. Walter Rübel, of Berlin, Germany, has recently patented a new alloy of magnesium and zinc which, in his specifications, he claims has a specific gravity of 1.8; when cast, presents a resistance of 15 kilos to 25 kilos; when rolled, from 25 kilos to 35 kilos, with a coefficient of expansion of from 8 per cent to 12 per cent. Satisfactory alloys of these metals cannot be produced from more than 99 per cent nor less than 94 per cent magnesium, and less than 1 per cent nor more than 6 per cent zinc. In case of materials that are to be rolled or pressed the zinc should preferably not exceed 3 per cent. Pure zinc is not essential, as good alloys can be made if the zinc contains copper, aluminium or metals of the iron group, as iron, nickel, chromium or manganese.

The alloy is prepared by carefully melting the magnesium with the exclusion of air and adding the zinc, when a readily fusible material results, which can be cast, wrought, rolled or machined like brass. The alloy presents the fracture of fine steel. (982,022, Jan. 17, 1911.)

The stack at the Great Falls (Mont.) smelter is 506 ft. high and weighs 34,000,000 lb. About 16,000 tons of brick were used in its construction. It will withstand a wind of 120 miles per hour.

New Methods of Obtaining Hydrogen.

In the Linde-Frank-Caro process for the separation of hydrogen from water-gas the basis of the process is the production in the first instance of water-gas. As is well known this is obtained by passing steam over red hot coke whereby the former is disassociated into free hydrogen and oxygen. The oxygen combines with the carbon of the incandescent coke to form carbon monoxide, while the hydrogen remains in a free state. In addition to these two gases, commercial water-gas also contains traces of carbonic acid and nitrogen to the extent of from 3 to 5 per cent of the total volume of the gas. Water-gas consists apart from these impurities of about equal parts of hydrogen and carbon monoxide.

There are a number of ways for the chemical production of hydrogen but by the application of fractional condensation it may also be obtained in the form of a gas by means of a very simple mechanical process. Separation of the carbon monoxide from the water-gas may be brought about by cooling the water-gas to the temperature of liquid air whereby the carbon monoxide is liquified—the conditions of liquification approximating to those of nitrogen—while as is well known much lower temperatures are necessary to liquify hydrogen.

In order to carry out this process on commercial lines, the carbonic acid in the water-gas is in the first instance extracted in some convenient manner, such for example as its absorption by caustic soda. The water-gas is then compressed to a pressure of 60 atmospheres by means of a three-stage compressor. The gas is then dried and passed into an apparatus in which it is subjected to a bath of liquid air. As the result of cooling in this bath of liquid air, the carbon monoxide liquifies and the hydrogen passes out of the apparatus in the form of a gas.

The carbon monoxide may be re-evaporated or otherwise collected as a by-product and utilized in other ways. It may be employed to drive a gas engine or it may be used as fuel under a steam boiler. By using it for power purposes the whole process becomes very economical as in this way the power necessary for the fractionation of the gas can be obtained.

The process is very inexpensive to operate and the apparatus requires very little attention.

The rights in the process for this country have been acquired by The Linde Air Products Company of Buffalo.

* * *

In this connection a paper by Director Richard Blum, of the Berlin-Anhaltische Maschinenbau Company, read before the Aero Club in Berlin is interesting, as the author discusses the different processes now available for producing hydrogen gas, with special reference to the filling of balloons. The paper is printed in full in the *Journal für Gasbeleuchtung* of Jan. 21 and 28.

The oldest methods of making hydrogen gas on a practical scale, used before the eighteenth century, were based either on the action between sulphuric acid on iron or on the passing of steam over iron filings heated to a temperature of red heat. The latter process has recently been taken up again and changed to a cyclic process by the Internationale Wasserstoff Company. They employ steel retorts filled with porous iron oxide. The retorts are placed in a furnace and are heated from the outside. When the temperature has risen to a sufficient degree water gas is passed through the retorts and the iron oxide is thereby reduced to a metallic iron. When all the iron oxide is reduced to a porous mass of iron, the passage of water gas is stopped and steam is passed through the retorts whereby hydrogen is formed and the iron is again oxidized. Then the passage of steam is stopped and water gas is again passed through the retorts and so on. In this way hydrogen is produced and the iron oxidized, and in the next stage the iron oxide is reduced again to metallic iron. It is advantageous to keep the furnaces in continuous operation. The hydrogen thus produced is very pure and is compressed in steel cylinders of 6 cu. m each to 150 or 170 atmospheres.

Numerous plants are in operation in Europe for the decomposition of water into hydrogen and oxygen by electrolysis. In an apparatus for this purpose built by the Schuckert Company the production of 1 cu. m of hydrogen and ½ cu. m of oxygen requires 13 hp-hours. According to the present author the process is expensive and requires a large floor space. But the hydrogen produced is very pure.

Enormous amounts of hydrogen gas are produced in the large works for the production of caustic soda and chlorine by electrolysis of common salt solutions. The hydrogen gas is set free together with the caustic soda at the cathode and the quantity of hydrogen gas produced is chemically equivalent to the quantity of the chlorine produced at the anode. The quantities are so large, compared with the demand which exists at present for hydrogen, that most of the hydrogen gas is passed unused into the air. The Griesheim-Elektron Company in Germany produces daily 20,000 cu. m of hydrogen gas of about 90 per cent to 97 per cent purity. In this case the cost of the gas is practically that of compressing and storing the hydrogen gas. Special railway cars are built in Germany for the transportation of 500 cylinders containing 2750 cu. m of hydrogen gas. Much of the gas used in balloon trips in Germany is procured in this way.

Another method for producing hydrogen gas is by means of certain metals or compounds which in contact with water or alkaline solutions develop hydrogen.[1] Such materials are aluminium, silicon, and calcium hydride.

The production of hydrogen from aluminium and caustic soda solutions was used in practice by the Russian army in their war with Japan. This method is expensive.

More recently the Griesheim-Elektron Company has placed on the market a so-called "activized" aluminium (aktiviertes aluminium), 1.25 kg of which yield 1 cu. m of hydrogen. In this case the aluminium is stirred with water in the gas producer. According to statements of the manufacturing company the cost of producing hydrogen by this method is about 12.5 cents per cubic meter.

The Siemens & Schuckert Company has worked out a process for the production of hydrogen from the reaction between silicon and caustic soda solution. Formerly steam was employed, but now the heat set free during the reaction is utilized for maintaining the proper conditions. The evolution of hydrogen gas takes place when a 25 per cent solution of caustic soda acts on silicon introduced in small quantities. The capacity of a transportable plant (placed on wagons and drawn by two horses) is 60 cu. m to 120 cu. m per hour, while stationary plants are built for capacities up to 300 cu. m per hour. The Italian army has such plants in operation. The process is elegant, but the cost is about 18.75 cents per cubic meter.

For the filling of balloons it is of great importance to have the hydrogen as cheap as possible, say, at a price of 2 cents to 4 cents per cubic meter. This is possible by some newer processes. The first one of these mentioned by Mr. Blum is that of Linde, Frank & Caro for producing hydrogen from water gas with the aid of fractional condensation. This process is described above. In Mr. Blum's paper it is mentioned that under conditions as that exist in Germany the cost of the production of hydrogen gas by this method ranges from 2 cents to 3.25 cents per cubic meter, according to the purity of the gas and the size of the plant.

Another process worked out by the Carbonium Company in Germany employs acetylene gas which is compressed to two atmospheres and exploded by an electric spark. The acetylene thereby dissociates into the elements carbon and hydrogen. The carbon deposits in form of lamp-black. The hydrogen is passed through large washers and stored. The German plant of this company was destroyed last summer by an explosion A condition for getting the hydrogen cheaply by this method is that there is a market for the lamp-black.

[1] The production of hydrogen gas from hydrone (made by the Roessler & Hasslacher Chemical Company) belongs to the same class.

Another method of the Berlin-Anhaltische Maschinenbau Company employs the system of Rincker & Wolter. The starting materials are oils, petroleum, benzine or any heavy hydrocarbons. The process has been first developed as a substitute for illuminating gas plants using bituminous coal. These plants can be so equipped that they produce in general illuminating gas and gas for heating and cooking, and in exceptional cases hydrogen gas.

Plants of this kind are also instilled on railway cars to ship them to any place where the hydrogen may be wanted. There are two gas producers lined with fire-brick. They are filled to three-quarters with coke. By means of a steam turbine and a blower air is blown into the gas producers and the coke blown red hot. The turbo blower is then stopped by means of an oil pump and oil is sprayed into a generator. The oil is gasefied at once with deposition of lamp-black, while the hydrogen gas is passed through a washer and cooler and dryer, etc. The capacity of such plants is about 100 cu. m or more per hour. The time required for putting the plant in operation is two or three hours; it is then able to produce hydrogen gas continuously.

Hydrogen gas plants are furnished from Germany to Austria, Italy, and Russia, so that there seems to be a market for hydrogen in Europe. In the past it has been restricted in this country.

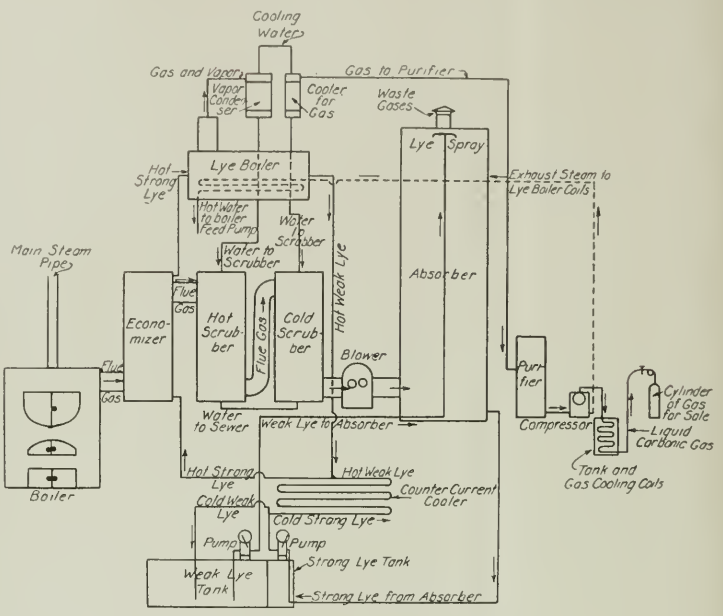


DIAGRAM OF CARBON DIOXIDE MANUFACTURING PLANT.

A Problem in Saving Heat in the Manufacture of Carbon Dioxide.

By Sterling H. Bunnell.

A very large business is done in the manufacture of carbonic gas for use by bottlers and others. This gas, pure carbon dioxide, is obtained from the combustion of coke, washed to take out sulphur and other impurities, separated from the other flue gases, dried, compressed to the liquefying pressure and bottled up in steel drums or cylinders for sale. The problems which must be solved in connection with making an economical plant for the manufacture of liquid carbonic gas entail almost every form of steam plant engineering.

The first operation in manufacturing is to burn the foundry coke under a steam boiler. A deep fire is carried and a forced draft used, so that the flue gases may have the highest possible proportion of carbon dioxide. With a properly designed furnace and good firing the proportion of carbon dioxide will run above 14 per cent and may at times reach above 16 per cent. The flue gases leaving the boiler setting are at a high temperature; this heat must all be disposed of before the gas is in condition for absorption. Here is the first point at which waste heat is to be saved. Accordingly, the flue gases are passed through an economizer, the duty of which will be explained later. The gases leave the economizer at a temperature below the boiling point of water.

The gases next pass through two scrubbers in succession, in which they are washed by showers of water to get rid of the cinders and whatever sulphur may be present. In this operation they are cooled to the temperature of the water supplied and this portion of the heat is necessarily wasted. The gases next pass through an absorber, in which they are brought in contact with lye solution. This solution has the property of absorbing carbon dioxide, so that the flue gases emerge from the absorber with a content of carbon dioxide of 10 per cent.

The lye solution from the absorbing tower is allowed to flow into a tank. This part of the solution is called the "strong" lye, because of its containing a considerable quantity of carbon dioxide. The next step is to pump the strong lye into a lye boiler, where it is heated above the boiling point, a portion of the water is evaporated, and a large part of the absorbed carbon dioxide driven off by the heat. Here again is a point at which heat must be applied continuously to a solution, and as the temperature required is little if any higher than 212°, exhaust steam from the power portion of the plant is used for the purpose of supplying heat. The lye solution returns from the lye boiler to a second tank and as its contents of carbon dioxide have been much reduced this solution is now known as the "weak" lye. In order to permit the weak lye to be again used for absorbing a fresh supply of carbon dioxide it must be cooled from its boiling temperature to perhaps 120°.

Observing that the weak lye from the absorber is cooled and must be heated, and the strong lye from the lye boiler is hot and must be cooled, the natural suggestion is to exchange the heat between the two solutions through a countercurrent cooler. This is of the double-pipe type, the hot weak lye from the lye boiler flowing through the inner pipes and the cold strong lye from the strong lye tank flowing through the outer pipes in the opposite direction. In this way an exchange of heat takes place which returns the weak lye at a temperature nearly as low as the temperature of the strong lye on its way from the tank, and delivers the strong lye at a temperature nearly as high as that of the weak lye coming from the boiler.

The strong lye leaves the countercurrent cooler at a temperature which is still considerably below the boiling point, and here comes in the opportunity to use the waste heat of the flue gases from the steam boiler by passing the strong lye through the economizer before mentioned. The strong lye leaves the economizer at a temperature near to boiling, and in passing

the economizer abstracts a large part of the waste heat in the flue gases.

All the waste heat in flue gases has now been accounted for. The bulk of the heat caused by the combustion of the coke has gone into the steam boiler and been devoted to the work of evaporation. This affords a good supply of steam available for doing the work of the plant. Most of the work required is for the compressors, which take the gas after it has been driven off the hot strong lye in the lye boiler and successively passed through coolers and dryers. Another portion of the steam is required for operating the pumps necessary for circulating the lye and for pumping cooling water about the plant. The exhaust steam from compressor and pumping engine still carries the latent heat which it received in the steam boiler. This large supply of heat is devoted to heating the lye in the lye boiler, evaporating a portion of the water and driving off the gas.

The skill required in designing and operating the entire plant is obviously devoted to arranging the closest possible balance between the heat transfers in all parts of the plant. The capacity of the plant—that is, the amount of carbonic gas that can be put into cylinders for sale—depends first upon the amount which can be driven off the lye in the lye boiler; a step further back, upon the proportion of the gas which can be recovered from the flue gases in the absorber; a step back of this, upon the proportion of the coke which can be burned into carbon dioxide rather than carbon monoxide, and this again depends upon the efficiency of the firing, the thickness of the bed of coke and the regulation of the draft, so that no free air shall pass through the fire. If the absorption of the gas is efficient the amount of coke burned, and therefore the grate surface, can be decreased. This will decrease the amount of steam made by the boiler, the available power of the plant and the amount of heat which can be recovered from the exhaust steam. Evidently, with a very efficient absorption it might be possible to produce enough gas from so little coke that there would not be steam enough to operate the plant, and in that case every possible saving in steam consumption by engines and all waste by radiation by steam pipes should be cut down as far as possible.

The operation of a complete modern plant for manufacturing carbonic gas would be a profitable study for any steam engineer interested in getting the most out of his steam plant. It is safe to say that very few steam plants of sizes in the neighborhood of 100 hp are constructed with any such degree of effort to reduce the usual losses to the minimum as is observed in the design and operation of the modern carbonic acid gas plant here described.

Griscom-Spencer Company,
New York City.

The ball-tube mill is being advocated by cyanide metallurgists as a machine that probably will give good results in preliminary crushing and grinding. These machines have given good results in the cement industry, and it is suggested that they could replace rolls in certain metallurgical operations. Either rolls or ball-tube mills would find preference with American engineers, who regard the use of the stamp as a coarse crusher as inferior to the machines mentioned.

The American Smelting & Refining Company has issued a statement showing a comparison of the condensed balance sheets for Oct. 31, 1910, and April 30, 1910. A similar statement is issued for the American Smelters Securities Company. Both statements show an improvement in earnings as compared with the previous year, and an increase in the quantity of metal held in process. President Guggenheim states that the April, 1911, statement will be more than usually extensive and comprehensive. He further adds that the supply of ore coming to the company's plants is showing a marked improvement, and that they have been encouraged to increase expenditures for improvement and new construction.

Centrifugal Clarifier and Filter

An article published elsewhere in this issue (page 147) contains interesting advance information on a centrifugal machine just perfected after many years' work by the DeLaval Separator Company for the continuous separation of liquids and solids. A smaller machine of the same company, which has solved a special problem of the separation of solids from liquids—namely, the separation of a small amount of sediment, etc., from a solution—has already stood the test of practice in the clarification and filtration of varnishes and allied products, oils, pharmaceuticals, patent medicines, fruit syrups and extracts, in fact, of many liquids containing either a sediment deposit or the finest flock or both. But as this centrifugal machine will undoubtedly prove useful beyond its present already large sphere of work the following notes on its construction and operation should prove welcome:

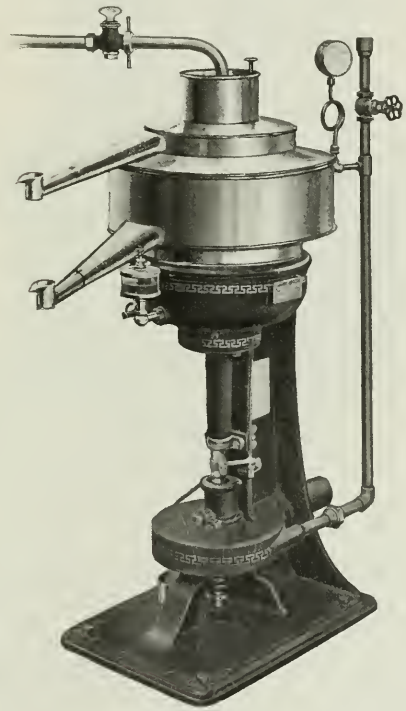

FIG. 1.—STEAM-TURBINE CLARIFIER AND FILTER.

An outside view of this machine is given in Fig. 1, which shows the steam-turbine style for direct steam connection. The largest size of this type has a height of 46 in. and requires a floor space of 18 in. by 24 in.—which indicates a big saving in floor space over other separating methods. In works where shafting is already installed the machine may be used with belt drive, while the smaller sizes of the machine are entirely practicable for running by hand.

Fig. 2 is a section of the clarifier and filter bowl. It contains the two compartments where the work is done, namely, the lower clarifying compartment and the upper filtering chamber. The clarifying compartment consists of a cylinder filled with a series of conical-shaped, pressed-steel disks, one above the other, about 1/32 in. apart and held rigidly in position by a central feeding device. The filtering chamber or upper section is also cylindrical in shape, but of less diameter.

The liquid first enters the bowl at the point *A* through the feeding device in the center and drops to the bottom of the clarifying compartment *B*, where much sediment is retained. It is then forced outward by the great centrifugal force through openings at the bottom to the periphery of the compartment *C*,

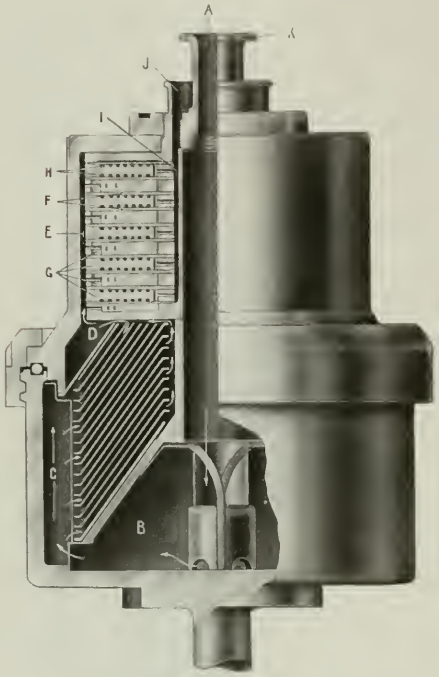

FIG. 2.—BOWL OF CLARIFIER AND FILTER.

where the bulk of heavier sediment is deposited. The liquid is next drawn to the center between the several disks. The purpose of these conical disks is to divide the liquid into thin layers, thus the friction on the disks above and below causes it to revolve rapidly and the heavier part, or balance of the sediment, is gradually forced to the under side of the disk above, whence down and out to the pocket *C*, while the thoroughly clarified liquid passes to the center and is forced upward and out into the second or filtering chamber at *D*. When the liquid enters this compartment fully 99 per cent of the sediment and foreign matter has been removed, thus leaving a small though very important work for the filter to accomplish.

The type used is what is termed the mutiple filter. The filter chamber is filled with a series of horizontal corrugated plates and perforated retaining rings, between which are placed one or more thicknesses of filter material, paper, felt, cloth or whatever may be best adapted to the work in hand. The liquid is forced from compartment *D* upward into the compartment *E*, which is a narrow space between the periphery of the filtering chamber and the filtering disks. This allows a channel for the liquid to pass up, from which it is delivered into the several compartments *F*, where it is forced through the filtering material *G* into compartment *H*. Here it is again forced to the center and upward through chanel *I* to the discharge point *J* and into the large cover from which it flows into the receptacle awaiting it.

The functions of the clarifying and filtering compartments supplement each other very thoroughly. The liquid is so thoroughly clarified by the disk system in the lower clarifying compartment that it leaves but a small amount of work for the filter to perform. Then, too, the filters being placed horizontally are substantially self-cleaning, for as the sediment or flock forms in any volume on the filters the centrifugal force throws it off and it is deposited at the outside or periphery of the compartments. Thus the filter material will do its work very much longer than is possible otherwise and continue to deliver a product of the required fineness.

This machine is built by the DeLaval Separator Company, 165 Broadway, New York City. The manufacturers state that with due care this clarifier and filter will last a lifetime. The average operator finds no trouble whatever in adjusting or cleaning any of the machine's parts and keeping it ever ready to perform its work. The chief advantages claimed for this machine are as follows:

The DeLaval clarifier and filter will take any product to which it is adapted immediately after compounding and deliver continuously (except for occasional cleaning of the machine) a finished article ready for the market. It thus greatly reduces the capital necessarily tied up in settling tanks with other methods.

On an average it will make a saving of 90 per cent in filter paper and cloths and their subsequent washing and cleaning over that required by other processes, also a saving of liquid absorbed by the filter paper and that lost by evaporation or dripping with other methods, a saving of liquid, labor and the

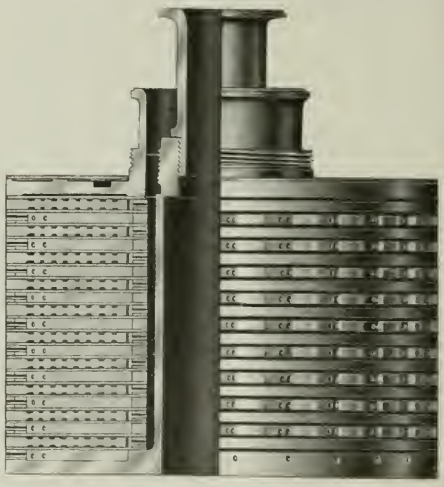

FIG. 3.—FILTERING CHAMBER.

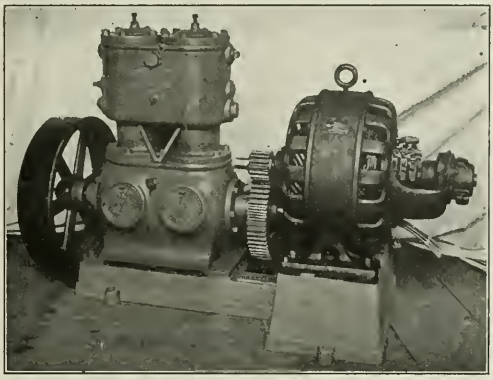
losses that sometimes occur from punctures in paper and a big saving in floor space.

Where it is desirable to aerate the products to be handled the DeLaval machine can be made to automatically aerate the liquids as they pass through it and thus do away entirely with the necessity of air pumps or other equipment and labor necessary for aerating purposes with other filtering processes.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in November, 1910, was 69. The total tonnage milled during that period was 1,843,941 tons of ore; 9746 stamps were in operation with an average duty of 7.32 tons per 24 hours. Tube mills in commission numbered 194. The yield for the month was 642,591 fine ounces of gold. Compared with the preceding month the only change of importance was in the increased number of tube mills in operation.

Sulphuric Acid Handled by Compressed Air.

In the manufacture of certain chemicals considerable danger, difficulty and expense are caused by the rapid deterioration of piping and receptacles with which the acids and fumes come in



MOTOR-DRIVEN AIR COMPRESSOR.

contact. The difficulties which the destructiveness of sulphuric acid, for instance, causes in pumping are well known.

The most satisfactory method of pumping destructive acids is that used by the Nichols Syndicate in their new plant at Bay Point, Cal. At one stage of the process of manufacture the acid is accumulated in a cylindrical tank which is provided with suitable inlet and outlet valves. When it is desired to pump the acid into other retainers the inlet valve is closed and air at from 60 lb. to 100 lb. pressure is admitted, which forces the liquid through the outlet valve to other parts of the plant. The flow of the acid is controlled by suitable valves in the piping system.

To meet the increasing demand for compressed-air apparatus for such work the United Iron Works, of Oakland, Cal., have brought out the motor-compressor shown in the above illustration. The compressor is a 6 x 6 Gardner Rix Duplex; speed, 2000 r.p.m.; pressure, 60 lb. to 100 lb.; capacity, 40 cu. ft. of air per minute. The compressor is driven by a Westinghouse type HF three-phase, 60-cycle, 550-volt motor.

This type of motor is admirably suited to this work. The secondary is phase wound and the three phases are connected to the three collector rings shown. In starting, the controller gradually cuts out the starting resistance which is connected to the secondary through the collector rings. This motor is so designed that an unusually high starting torque is developed, with comparatively low starting current.

The European Spelter Convention has announced that present prices will be maintained through March, but that on April 1, 1911, there will be an advance of 0.25 mark per kilogram. A graduated price list, with concessions for wholesale purchasers, will be adopted.

Determining the Accuracy of Indicator Springs

By E. K. Uebe.

The indicator is unquestionably the most necessary instrument for the operating engineer in a steam plant.

The indicator diagram is the only means by which to ascertain the action of the steam in the engine cylinder, to determine the efficiency of an engine and to detect internal wastes. It is, therefore, of vital importance that the indicator can be relied upon to be absolutely accurate in its performance, which especially applies to the piston spring, the most essential part of the indicator.

Unless the exact tension of the spring is known errors will result from its use and the determinations made with the indicator will be of little or no value. An instrument for testing indicator springs has recently been placed on the market by the Schaeffer & Budenberg Manufacturing Company, of Brooklyn, N. Y.

The instrument, a general view of which is given in Fig. 1, consists essentially of a closed vessel made of cast iron capable of resisting internal steam pressures up to 200 lb. per square inch. The steam pressure in the vessel is measured by a gage of special construction consisting of a piston of ½ sq. in. area and which is free to move in an inclosing cylinder.

The lower portion of the piston is pointed and rests in a yoke which is suspended on the knife-edge of a pair of scales mounted on top of the closed vessel. If the scales are previously balanced, before admitting steam into the vessel, it is evident that the reading of the scales will give the pressure

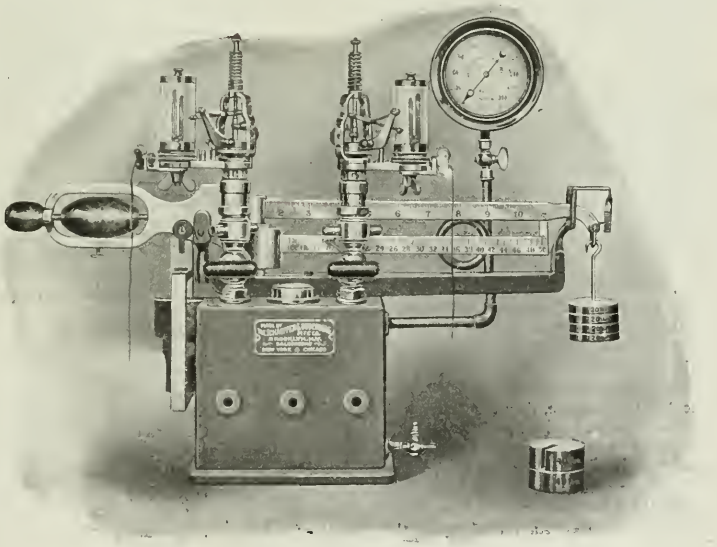


FIG. 1.—APPARATUS FOR DETERMINING THE ACCURACY OF INDICATOR SPRINGS.

acting on each element of the vessel equal in area to that of the piston. The scales are graduated to fiftieths of a pound, which permits of very close readings.

In testing indicator springs steam is turned on into the vessel to gradually warm it and allowed to blow through the connections and indicator cocks to remove any particles of dust or grit which may have accumulated there. Steam is then shut off again and the indicator screwed in its place, putting paper on the indicator drum, on which paper two vertical lines are ruled as 1-2 and 3-4 (see Fig. 2).

The indicator pencil is pressed against the drum and a horizontal line *Q Q* is drawn at the point thus marked. Then

the poise of the scale is set, say, 5 lb. and steam is admitted into the vessel, gradually rising in pressure until the scale floats. When the pressure is exact the line *R R* is drawn, and so on for successive pressures of 5 lb., until the limit of the scale is reached. During this operation the motion of the indicator pencil is continuously kept upward. If at any moment the pressure rises too high it is lowered by manipulating the valves below the required amount and then gradually raised to the desired point.

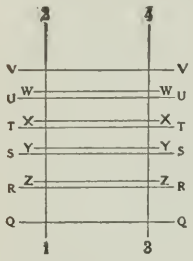

FIG. 2.—RECORDS OF TESTS.

When the indicator pencil has reached its highest position the steam pressure is allowed to fall gradually and a series of similar lines, as *W W*, *X X*, *Y Y* and *Z Z*, drawn during the descent of the piston. The motion being continuously downward. The distance between any two of these lines, as *Z R* or *Y S*, indicates the loss due to friction of the indicator.

The special advantage of this machine, besides its absolute accuracy, is that the indicator springs are tested in the individual indicator in which they are used and under actual steam pressure which is as near to the actual working conditions as possible.

The indicator spring-testing apparatus serves also for testing pressure gages which can be connected to the three openings in the front side of the vessel provided for that purpose, and the readings are verified by the indications on the scales and the test gage shown in the illustration.

A New Recording Gas Meter.

A new meter for indicating, integrating or graphically recording the quantity of flow of gases at any pressure and at any temperature (independent of fluctuations of pressure or temperature) has recently been designed by Prof. Carl C. Thomas, of the University of Wisconsin, and has been placed on the market by the Cutler-Hammer Manufacturing Company, of Milwaukee, Wis.

The operation of the meter is based on a simple and interesting principle which will be understood from the diagram, Fig. 1, which shows a passage *A* through which gas is flowing in the direction of the arrow. Within the passage is an electric heater *B* made of a suitable resistor, and two electric resistance thermometers *E* are provided at the entrance and exit of the passage way. Now suppose that the voltage at the heater terminals remains constant and that the resistance of the heater does not change, then the heater will give off heat to the gas at a constant rate.

If now the rate of flow of the gas remains uniform and constant, the gas is raised by the heater in temperature by some fixed number of degrees, shown by the difference of the readings of the two thermometers *E* and this temperature difference will remain constant so long as the conditions do not change. On the other hand, if the rate of flow of gas increases (while the liberation of heat from the heater remains constant) the larger quantity of gas passing in a given time will be raised less than before in temperature; that is, the temperature difference measured by the two thermometers *E* will be smaller than before. Conversely, if the rate of flow of gas decreases, the temperature difference betwen the two thermometers *E* will increase. In brief, as long as the rate of liberation of heat from the electric heater is kept constant the temperature difference between the two thermometers *E* varies inversely as the rate of flow of gas, and can, therefore, be used as a measure of the rate of flow of gas.

The inherent weakness of this method, as just stated, for commercial service is that it requires the maintenance of an exactly constant rate of liberation of heat from the electric heater. This is a condition difficult to fulfill in commercial service. Therefore, for commercial-service meters the principle of operation has been modified. The change is as simple as it is ingenious.

Not the rate of heat liberation is maintained constant and the temperature difference between the two thermometers *E* measured, but the latter temperature difference is maintained constant artificially by varying the rate of heat liberation from the electric heater—that is, by varying the electrical power supplied to the heater. Hence the temperature difference between the two thermometers *E* remains constant and the varying input of electric power in watts supplied to the heater is measured and serves as a measure of the rate of flow of gas. The watts are measured by recording wattmeter or integrating wattmeter.

The two resistance thermometers are in the form of ruggedly made screens of resistor wire, so disposed as to come in contact with all the gas passing through the meter. They form two arms of a Wheatstone bridge, which by means of the deflection of the galvanometer needle causes the controlling mechanism to cut in or out enough electrical energy so as to keep the temperature difference between the two resistor wires *E* constant. There is no necessity to go further into details as the principle is clearly one of electrical resistance thermometry, which has reached such a high state of excellence in recent years.

The accuracy of these meters is not affected by changes in pressure of the gas or air, since the unit of measurement is that of weight rather than that of volume—that is, the meter takes cognizance of the specific gravity. Also variation of temperature of the incoming gas does not effect the accuracy of the meter because it is a difference of temperature, rather than a fixed temperature, upon which the measurement depends. The meter can, therefore, be used for gas or air at either high

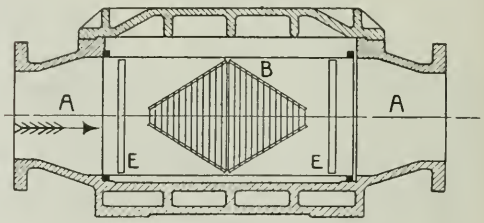

FIG. 1.—DIAGRAM OF GAS METER PRINCIPLE.

or low pressure, and at either high or low temperature, provided the materials used in construction are suited to the conditions.

The meter is especially well adapted for measuring the discharge of gas or air from compressors, blowers, etc., because the small and rapid periodic fluctuations of pressure, due to either suction or discharge conditions, do not interfere with the steady action of the thermometers. The time lag of the latter is sufficient to smooth out the curve of watts input or of temperature variation, as the case may be, and true average results are thus indicated. The fact that the meter is capable of accurately measuring gas under varying pressures and temperatures makes it especially valuable for measuring natural gas, as well as compressed air.

The electrical power required to operate the meter is approximately 1 kw per 75,000 cu. ft. per hour at atmospheric pressure.

The Thomas meter is essentially applicable to the measurement of gas or air which is either dry, saturated or superheated. If water is carried along mechanically as a fog or mist (as may be the case in blast-furnace gases coming from the cleaning apparatus) the evaporation of this by the meter itself, of course, interferes with making accurate measurements. But such fog or mist can readily be transformed into dry vapor by the introduction of heat from a small steam radiator consisting of a coil of pipe in the entrance to the

meter. Steam is usually available, and can be introduced at about atmospheric pressure or above, as may be most convenient. A very small amount of steam suffices for this purpose.

Let us now briefly consider the theory of the meter.

Let G = cubic feet of gas per hour,

E = energy in kilowatts,

then B.t.u. per hour = 3412 E.

T = temperature difference, deg. Fahr.,

S = specific heat per cubic feet.

The GST = heat energy equivalent to E, or

$\frac{GST}{E} = \frac{3412}{S}$ = constant K which depends upon the specific heat of the gas. For a gas of constant specific gravity the value $GT \div E$ is, therefore, a constant.

That this is correct is brought out by experimental tests, the results of which are given in Fig. 2. The abscissas give values of $T \div E$ or degrees of temperature rise per kilowatt of electrical input. The ordinates give values of G or cubic feet of gas per hour. Since according to the above formula $GT \div E$ should be a constant, the curves of Fig. 2 should be rectangular hyperbolas. This is indeed the fact.

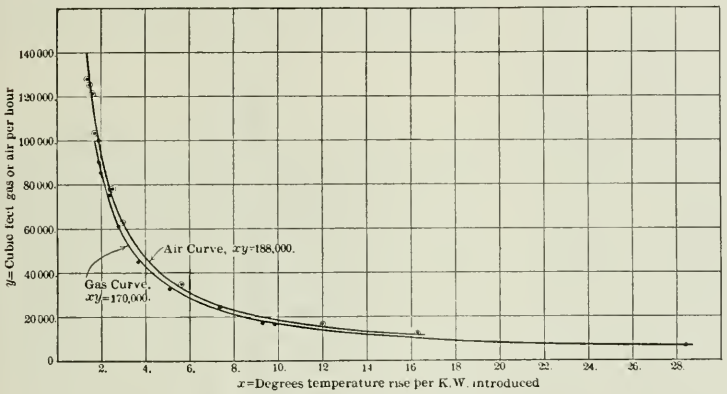

FIG. 2—RESULTS OF TESTS OF GAS METER.

Since the temperature difference T is kept constant it follows that $\frac{K}{T}$ is constant. Let $\frac{K}{T} = C$. Then $G\frac{KE}{T} = CE$.

It can now be shown that if the specific heat of gas made under given conditions be calculated from the customary chemical analysis and the specific heat of the constituents, then this specific heat may be used for determining the constant C. From the gas curve (Fig. 2), which was made with illuminating gas at an average temperature of 59° Fahr. and under an average absolute pressure of 6 in. water and 29.8 in. mercury.

$$K = 170{,}000 = \frac{3412}{S}$$

Therefore, for the condition of the gas when the tests were made the specific heat per cubic foot, $S = \frac{3412}{170{,}000} = 0.0201$. If this be reduced to standard conditions of 32° Fahr. and 29.9" mercury then $S = 0.021$, which is to be compared with the calculated specific heat, giving $S = 0.0211$.

If the standard conditions are taken as 62° Fahr. and 29.9" mercury the specific heat becomes 0.0198 and the constant becomes $K = \frac{3412}{0.0198} = 172{,}500$, nearly.

If the temperature difference is kept constant at 2° Fahr., then $\frac{K}{T} = \frac{172.500}{2} = 86{,}250 = C$, or $G = 86{,}250\,E$.

The cross-section paper on the recording watt-meter is ruled so that 86,250 E is read directly, instead of the watts E. The record is thus read directly in cubic feet of gas.

The regular records of chemical analysis of the gas should be referred to from time to time in order to ascertain what percentage variation, if any, takes place in specific heat. It appears that the elements which vary during the operation of a gas plant are not those whose variation produces serious variation in specific heat. The variation that does take place is apparently well within the limits of accuracy practicable, or generally considered necessary in the operation of gas plants. By making frequent chemical analyses the error can be reduced so as to be quite negligible.

The conditions during the air tests of Fig. 2 were as follows: Barometer, 29.75; pressure, 6.5 in. water; average temperature of air as measured in the wet meter, 60° Fahr. From the air curve obtained under these conditions (Fig. 2). $K = 188{,}000$, and $S = 3412 \div 188{,}000 = 0.0181$.

Reducing this to standard conditions of 32 and 29.9 in. mercury, $S = 0.0191$. This is to be compared with the accepted specific heat of air under these conditions, or 0.0192 b.t.u. per cubic foot.

This is probably excellent evidence of the accuracy of these tests and of the meter.

Aside from its accuracy, based on the correct application of exact specific principles, the Thomas gasometer has some obvious great practical advantages. Compared with a wet gas meter, such as is commonly used for measuring the flow of gas, the Thomas meter is very much smaller for the same capacity. Moreover, its switchboard may be placed at a distance from the pipes through which the gas flows, if this is desired, thus permitting the recording mechanism to be installed in the office, where the records made are under constant observation.

Electric Iron Smelting.

From time to time notices have appeared in our columns on the Grönwall, Lindblad and Stalhane (A. B. "Elektrometall") process of electric iron smelting, and in our last issue (page 111) we mentioned the starting of a furnace of this type at Trollhattan, Sweden, and gave some of the results obtained with it. It should now be of interest to sum up briefly the progress which has recently been made in the introduction of this process, for which the British, United States, Mexican and other rights have been acquired by Electro-Metals, Ltd., 9½ Union Court, Old Broad Street, London, E. C.

At the meeting of the Iron and Steel Institute in May, 1909, a paper describing this process was read by Mr. E. J. Ljungberg, chairman of the Stora Kopparbergs Bergslag's A. B., Sweden, at whose Domnarfvet iron works the experiments had been carried out. Later an exhaustive report on the experiments by Mr. Lars Yngström, managing director of the company, was published (our Vol. VIII, page 11, January, 1910). This report, which gave a complete description of the furnaces, showed that a technically and commercially successful process of electric iron smelting had been developed. We will in the following briefly survey the progress made in the practical application of the process.

In its home country, Sweden, the importance of the process was quickly recognized, more especially because the conditions

of the country are favorable for electric iron smelting. High-grade iron ore is abundant and the numerous waterfalls of the rivers furnish a source of electric power at low cost. In addition the country lacks coal and the iron industry therefore mainly depends on charcoal for fuel which is constantly growing more scarce and costly. The possibility of replacing about two-thirds of the quantity of fuel by electric power together with the prospect of still further improving the quality which has made Swedish iron famous has therefore made the new process a matter of national importance, and it has been taken up as such.

There exists in Sweden an institution called "Jern-Kontoret" which is an association of practically all iron and steel manufacturers in the country. This association is over 150 years old and plays a very important part in the Swidish iron industry. Its object is to suppply technical and financial assistance to the members and generally to promote the iron industry of the country.

After careful consideration of the results of the Domnarfvet experiments the board of directors of "Jern-Kontoret" determined to enter into an agreement with the patentees and make an appropriation of money for a plant to thoroughly investigate the process. The fact that this is the first occasion in its history that the association has embarked on a technical undertaking on its own account proves the importance attached to the process. The Swedish Government also offered to assist in the undertaking by supplying electric energy at a nominal cost from their large power plant at Trollhattan.

This installation has now been in operation since the middle of November. It comprises a furnace for 2,500 hp and is elaborately fitted with the best appliances for exact scientific research. It may be safely predicted that the results of work carried out under such auspices will prove of the greatest value and interest.

It is not to be expected that any official report on this work will be available for a considerable time to come, but we are in a position to state that the results so far are highly satisfactory. Some numerical results were given from absolutely reliable private correspondents on page 111 of our last issue. The experience with the experimental furnace naturally suggested various improvements which have been embodied in the new furnace and have proved of great importance for the smooth and economical working of the process.

Meanwhile private enterprise has not been idle. At the conclusion of the experiments by the inventors the experimental furnace at the Domnarfvet Iron Works was taken over by the owners, the Stora Kopparbergs Bergslag's A. B., who continued to work it for their own purposes. They are now constructing a new furnace for 4000 hp which is the first of a number of similar furnaces planned for a total of about 40,000 hp. The works contemplated will have an annual capacity of over 120,000 tons of pig iron and the cost is estimated at upward of $3,500,000.

Another well known Swedish iron works, the Uddeholm Company, have purchased a license and are about to put down a plant of three furnaces for 3000 hp each. Other Swedish works have also acquired licenses for construction and propose to erect works on similar lines.

The new conditions pertaining to electric iron smelting appear likely to foster an iron industry in some countries which have hitherto not produced iron. An example of this is Norway. The ores of this country are mainly of low grade and no coal is found there. Up to the present time no iron has, therefore, been produced there. Water power is, however, abundant and charcoal can be produced. There has now been formed a company which has acquired the Norwegian patent rights to the "Elektrometall" process and is putting down works at Tyssedal near Hardanger. These works will comprise two furnaces for 3000 hp each. Another company has been formed for putting down works at Bilefoss near Arendal, where about 30,000 hp will be utilized for iron smelting.

Similar conditions bid fair to create an iron industry in more distant countries where the cost of freight would enable a native electric iron industry to compete successfully with imported iron and steel. We are informed that Electro-Metals, Limited, are engaged in a number of important negotiations for electric iron smelting plants in several over-seas countries.

The quality of electrically produced iron has proved decidedly superior to that of ordinary pig iron from a similar grade of ore. It will readily be seen that this must be the case, as the sulphur contents can be very much reduced in the furnace and a very dense and tough material is obtained on account of the absence of gases in the iron.

Considering the developments which have already taken place it is safe to predict that this process is destined to play a very important part in the industrial life of many countries and that we may expect to see iron production established in various parts of the world where cheap electric power rather than an abundance of coal determines the prospects of economical success. Canada and California seem particularly in line for such developments.

NOTES

Society of Chemical Industry.—At the meeting of the New York Section of the Society of Chemical Industry, on Feb. 24, the following papers were read: On "A New Treatment of Water, Preventing Scale in Boilers Without the Use of Chemicals, by Aid of Aluminium Plates," by Mr. Thomas R. Duggan; and on "Boiler Water Purification," by Mr. William M. Booth.

A Congress of Technology will be held in Boston on April 10 and 11 to fittingly mark the fiftieth anniversary of the Massachusetts Institute of Technology. A large number of technology graduates, who have been conspicuously successful in varied lines of engineering, will present papers at the congress discussing the conditions and prospects in specific industries.

The American Mining Congress has recently increased its board of directors from nine to thirteen, and has adopted a plan for the organization of State chapters. The next meeting place of the congress probably will be in Chicago. Secretary Callbreath is now in the East in connection with the work of the congress, and will arrange for the 1911 meeting.

Enameled Sills.—The Stuart & Peterson Company, of Burlington, N. J., has recently completed the job of re-enameling two mammoth chemical stills of Parke, Davis & Company, each weighing 6500 lb. and having a capacity of 650 gal. These stills were originally of German make, but after several years of constant use re-enameling become necessary. To carry it out the Stuart & Peterson Company had to erect a special building and oven. The enamel used is the acid-resisting enamel of the Stuart & Peterson Company.

Refractory Cement.—The H. W. Johns-Manville Company, of New York City, have just placed on the market a line of refractory cements for furnace settings of various types, cupolas, lining brass furnaces, assayers' crucibles, oil burning, tilting and rotary furnaces and for patching and facing brick in the fire zone under various conditions. These cements are rated to resist temperatures as high as 3000° Fahr. (about 1650° C.). The same company has also developed a coating for walls known as brickline cement which prevents clinkers from adhering and to seal the pores of the brick.

Titanium Steel Rails.—The New York Central Lines have ordered 41,500 tons of titanium bessemer rails for 1911, specifying the use of 1 per cent of the 10 per cent ferrotitanium. This alloy is made, according to the patents of Rossi, by the Titanium Alloy Manufacturing Company, of Niagara Falls. This order will, therefore, require more than 400 tons of the 10-per cent alloy, which is believed to represent the largest single order ever placed for alloy steel rails.

Instruments of Precision and Laboratory Apparatus is the title of the handsome new 120-page catalog of Messrs. Wm. Gaertner & Company, of Chicago, giving illustrated descriptions of their numerous instruments of precision (microscopes, telescopes, slide rules, dividing machines) and laboratory apparatus for the demonstration of the phenomena of mechanics, accoustics, heat, light and electricity. Among other instruments Messrs. Wm. Gaertner & Company are the original manufacturers and the co-designers of the apparatus described in Millikan's Molecular Physics and Heat, in Millikan & Mills's Electricity, Sound and Lights, and in Millikan & Gale's Laboratory Course in Physics. The firm has just moved into their new fireproof office and showroom.

Recording Thermometers.—We have received from the Bristol Company, of Waterbury, Conn., their illustrated 40-page catalog of Bristol's class III recording thermometers, including a description of the new compensated gas-filled thermometers which are being used for a great variety of applications for recording temperatures up to 800° Fahr.

PERSONAL

Mr. **Sterling H. Bunnell** has resigned his position as works manager of the Griscom-Spencer Company to open an office at 90 West Street, New York, as a specialist in factory system and consulting engineer. Mr. Bunnell is the author of "Cost Accounting for Manufacturing Plants," about to be issued by D. Appleton & Company. Mr. Bunnell has been retained by Messrs. Clinton H. Scovell & Company, certified public accountants of Boston and Chicago, to take charge of the cost keeping and factory efficiency branches of their work and will also represent them in New York.

Mr. **J. M. Callow**, of the General Engineering Company, Salt Lake City, was in Denver and Leadville, Col., recently on professional business.

Mr. **John Collins Clancy** has been in Denver several times recently conferring regarding the first installation of his process at Victor, Col.

Mr. **J. V. N. Dorr**, metallurgical engineer of Denver, has returned home after spending several months in England.

Mr. **J. R. Finlay**, who has been general manager of the Goldfield Consolidated Mines Company for the past year, has resigned his position.

Mr. **H. W. Hardinge**, of New York, is on a trip through the West on professional business and for the purpose of investigating the subject of ore reduction, in which he is specially interested.

Mr. **Richard Lindenberg** and Prof. **F. R. Eichhoff** are expected to arrive in New York on March 7. Mr. Lindenberg, who has not been in this country since 1904, is the president of the Lindenberg Steel Works, of Remscheid-Hasten, Germany, which were described in detail in our October issue, 1910 (Vol. VIII, page 563), and which are particularly interesting as they were the first German works to introduce on large scale electric steel refining by the Héroult process. Professor Eichhoff was formerly the managing expert of the Héroult-Lindenberg electric furnaces and now occupies the chair of the late Professor Wedding at the Royal School of Mines in Berlin.

Mr. W. H. McFadden has tendered his resignation as vice-president and general manager of Mackintosh, Hemphill & Company, Pittsburgh, to take effect March 1, 1911, and same has been reluctantly accepted by the directors. Mr. McFadden has been closely identified with the rolling mill industry for the past 25 years and has taken an active part in the construction and installation of many of the most important steel mills in this country. Mr. McFadden will divide the next few months between looking after his important gas and oil interests and in traveling for his health.

Mr. **William McLaughlin** has been appointed mill manager of the Alvarado Mining Company.

Dr. **Robert H. Richards** recently made a trip into the zinc district of Missouri for the purpose of inspecting the work of the jigs and classifiers designed by him.

Dr. **L. D. Ricketts**, manager of the Cananea Consolidated Copper Company, Mexico, is taking a vacation in Europe.

Mr. **R. W. Robbins** has been appointed superintendent of the McKinley-Darragh property at Cobalt, Ontario.

Mr. **Dennis Sheedy**, vice-president of the International Smelting Company, recently made a trip of inspection to the company's smelter and other properties.

Mr. **L. C. Triplett** has resigned his position as mill manager of the Alvarado Mining Company, Mexico, and has accepted a similar position at Guanajuato for the Guanajuato Development Company.

OBITUARY

Edward Balbach, Jr., president of the Balbach Smelting & Refining Company, Newark, N. J., died on Dec. 30, 1910, after a short illness. Mr. Balbach was born in Carlsruhe, Germany, in 1839, and came to the United States in 1850. Together with his father, Edward Balbach, Sr., he was a pioneer in lead smelting and refining, and in copper refining by electrolysis. He first introduced improvements in lead refining by desilverizing with the addition of zinc, and recovering about 50 per cent of the zinc by distillation. For many years the Balbach works were one of the few sources of refined lead in this country. In copper metallurgy Mr. Balbach did important work in constructing and operating the first electrolytic refinery in the United States in 1881, which was the forerunner of a great industry in which the United States holds the first position. The history of this pioneer American copper refinery was given in our Vol. II, page 303. In the death of Mr. Balbach the metallurgical profession has lost an able and energetic worker who was worthy the high position accorded him by his associates.

Walter L. Pierce, who for thirty-two years had been connected with the Lidgerwood Manufacturing Company and for twenty-nine years its secretary and general manager, died of heart failure at his winter home in the Hotel St. Andrews, New York City, Dec. 10, 1910. He was a son of John F. Pierce, and was born at Dorchester, Mass., on June 8, 1855. His parents survive him, and he leaves a widow, Jane Hutchins; an only son, Walter L. S. Pierce; a brother and a sister. He was known to a wide circle of personal and business associates. He was remarkable as an organizer, and so perfect was his work that no detail of the great business which grew up under his hand was neglected during his long absences from his desk while seeking health, and the coherent body which he formed is a monument to the efficiency of his work. Besides his connection with the Lidgerwood Manufacturing Company he was treasurer of the Hayward Company and of the Gorton-Lidgerwood Company. One of Mr. Pierce's most intimate and life-long friends said of Mr. Pierce: "His unselfish life is his eulogy, and words in lending themselves to praise his steadfast soul do most honor themselves. Given to mingle in the everyday affairs of life, he dignified them in that he added to the world's store of men's confidence in each other. Tenacious in application, indomitable in courage, he was master of his calling in life, but not before he was master of himself. Experience and knowledge were not, however, for him to hoard, capital for accumulation to himself, but rather he gave of himself generously, and no worthy plea so weakly pressed that did not meet a quick response." It will not be out of place to acknowledge here the friendly sentiment which Mr. Pierce always maintained toward this journal since the early days of its foundation.

Charles F. Shelby, general metallurgical superintendent of the copper smelter of the Cerro de Pasco Mining Company in Peru, was killed in an automobile accident between Lima and Ancon, Peru, on Jan. 25, 1911.

Mr. Shelby was among the prominent and able metallurgists in the copper industry. He was born at Omaha, Neb., in 1874. His first professional employment was as assistant chemist at the Globe smelter, Denver. He left this plant in 1900, going to Aguascalientes, Mexico, where he was chemist and later assistant superintendent. In 1903 he entered the field of copper metallurgy under the able direction of Dr. L. D. Ricketts, at Globe, Ariz., where he acted as superintendent of the Old Dominion Copper Company's reduction works. In 1906 he accepted a more responsible position at Cananea, where he inaugurated many improvements in copper metallurgy and aided in bringing the works of the Cananea Consolidated Copper Company to a high state of efficiency. Early last year he was selected as superintendent of the Cerro de Pasco Mining Company, and in company with Mr. A. B. W. Hodges as general manager, went to Peru.

Mr. Shelby was a constant contributor of valuable notes and articles to the technical press, following in this respect the liberal policy of his employers in giving the profession the benefit of his ingenuity and ability.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Ore-Treatment.

61,866, Feb. 5, 1867, Julio H. Rae, M. D., of Syracuse, N. Y.

Gold and silver. The crushed ore is placed in the bottom of a glass jar upon a platinum anode plate and around a revoluble platinum-wire cage anode. The dissolved metals are reprecipitated upon a sheet of copper in the solution above the ore.

79,744, July 7, 1868, A. L. Fleury, of New York, N. Y.

Precious metals. Silicious ores, which may be mixed with chemicals, are heated and subjected to chemical gases in a shaft furnace. The treated mass is removed into a closed heated vessel, wherein it is subjected to the action of water, steam and electricity.

90,565, May 25, 1869, William John Lynd, of Golden City, Col.

Removes iron, copper and other discoloring matters from clay by passing an electric current through water containing the clay in suspension.

101,009, March 22, 1870, Nathaniel Haskell, of San Francisco, Cal. Assignor to himself and Joseph F. Steen, of same place.

Copper. The ore is placed in heaps on a hillside where the ground is not porous. A trench is dug around the ore heaps leading to a vessel or vessels below. The ore is alternately drenched with water and exposed to the air for several days. The resulting weak solution of copper sulphate is electrolyzed in the vessels, the copper being preferably electroplated upon metal articles.

239,300, March 22, 1881, Andrew Ryder, Oakland, Cal.

Ore is disintegrated by heating it and dumping it into a liquid carrying an electric current. The apparatus illustrated is a tank containing opposed downwardly converging copper-plate electrodes, the heated ore being dumped between them.

246,201, Aug. 23, 1881, Emile Reynier, of Paris, France. Assignor to Simon Philippart, the son, manager of La Force et la Lumière Société Generale D'Electricite, of Brussels, Belgium.

The ores are used as soluble electrodes in a two-fluid voltaic cell. The anode and cathode compartments are separated by a diaphragm of paper, cloth, skin, membrane or felt. One compartment contains an anode of zinc or lead, or fragments of galena, calamine or other rich conducting ores, a lead or zinc plate conductor being placed on the ores. The anode solution is caustic soda or potash. The other compartment contains a copper solution, e.g., sulphate. The zinc or lead dissolves and is recovered with regeneration of the caustic alkali. The other metals, e.g., silver, remain as residues. Copper is simultaneously deposited in the other compartment. The cell generates an electric current which is externally utilized. The process is applicable to ores containing also nickel, cobalt, mercury and gold.

272,391, Feb. 13, 1883, Antonin Thiollier, of Villeboeuf de Roche la Moliere. Assignor of one-half to Albert Ancel, of Chateau de Bouches D'Uzure, Canton de Craon, Mayenne, France.

The crushed ores are placed around carbon electrodes in a series of parallel vertical receptacles having perforated walls. The electrodes of opposite polarity are placed between the receptacles with their lower edges in gutters to catch deposits. Beneath the receptacles and electrodes is an open space containing steam-heated coils. The receptacles may be of wood, wickerwork, gutta percha, rubber or coated sheet iron. If the ore is very fine they are lined with cloth or felt. If the ore is a poor conductor coke or plumbago is mixed with it, being separated from the residue and re-used. The cells may have a tight cover to retain fumes. When the electrodes in the ore are anodes, the collecting electrodes between the receptacles may be plates of copper. When the electrodes in the ore are cathodes the intermediate electrodes are insoluble, e.g., carbon. For ores of gold, silver and platinum the embedded electrodes are made anodes. For silver ores a solution of sodium sulphate or nitrate, or of hot sodium chloride may be used, or a cyanide solution. For gold or platinum sulphates nitrates, cyanides, sodium chloride or caustic soda or potash are available. Where the ore contains two or more of these ores sodium chloride is preferably used. If the ore contains silver chloride an ammonia, ammonium chloride, hot sodium chloride or cyanide solution is used. For silver-sulphide ores an ammonia or hot sodium chloride solution is used. For gold telluride ores a sodium chloride or cyanide solution, the ore being placed around the anode, or a sodium chloride solution, the ore being placed around the cathode, in which case the gold deposits at the anode as auric acid. Ores containing gold, silver, lead, copper, iron and metalloids are treated with a hot solution of sodium chloride. The gold, silver, copper and lead deposit at the cathode. Iron remains in the vessel as an oxide. Zinc ores are placed around the anode, ammonia, ammonium carbonate, soda and potash solutions, etc., being used. Ores of lead may be treated with a hot solution of sodium or lead chloride, or with a caustic soda solution. Silver may be parted from lead and zinc. For antimony ores a hot potash solution is used; for mercury ores a solution of the sulpbate, nitrate or bichloride of mercury. Copper ores are variously treated, refractory ores being roasted, and ammonia, ammonium carbonate or potash solutions used. Nickel ores are roasted and ammonia or ammonium carbonate solutions used. Ore containing carbonate of iron and calcium may be electrolyzed in a solution of sodium or iron chloride, chemically pure iron being deposited and lime remaining as a residue.

BOOK REVIEW.

Welding.—By **Richard N. Hart**, B.S. 8vo., 181 pages, 93 illustrations. Price $2.50 net. New York: McGraw-Hill Book Company.

The four principal chapters are devoted to ordinary welding, electric welding, hot-flame welding, and thermit welding. The descriptions are good, illustrations and photographs first class, and the whole constitutes a useful and instructive book. In his preliminary remarks the author is sometimes hazy in his statements, and his English is at places faulty, but the practical part is well written, clear, and direct. It is a good practical book.

History in the Making.

When in the course of human events an ideal is made a reality, history is being made. The opening of the Chemists' Building in New York is a milestone in the history of chemistry in America. In its stately simplicity and dignity it is a monument to the idealism of its builders. In its equipment and facilities it is a great endowment for future service. This ideal was realized without outside help through the combined efforts of American chemists. A few years ago the question might have been raised whether American chemists could do it. They could, they would, they did. And future historians will speak of the opening of the Chemists' Building as the beginning of a new epoch in the history of chemistry in America.

This was the first step—and it is always the first step that counts. Next year an International Congress of Applied Chemistry will meet for the first time on American soil. The American organization has been perfected and tentative rules have been formulated, which will be found on page 173 of this issue. We gladly place our correspondence columns at the disposal of our readers for critical discussion. For all agree that next year's Congress must be made a grand success, worthy of America and American chemistry.

Smelting Fine Ore.

One of the great sources of loss in the smelting of base metals, particularly copper, is the escape of fine ore in the reduction process. It is frequently the case that the fine ore is of high grade and then the loss becomes more serious and the ingenuity of the metallurgist is taxed to provide a suitable remedy. Naturally, in all preliminary treatment, such as concentration, every effort is made to produce as coarse a product as possible and to avoid the production of fine concentrate, but when the mineral is finely disseminated through a large amount of gangue and occurs in small crystal masses, fine grinding and concentrating become a necessity. Then arises the problem of the best disposition of the fine ore.

Various solutions have been proposed, and some adopted. In one instance the fine concentrate is mixed with concentrator slime and furnace flue dust and briquetted. The briquettes are sufficiently strong to stand the subsequent handling and are used as part of the blast-furnace charge. This scheme offers quite a satisfactory method of disposing of these three troublesome products, although the quantity of slime which can be used is not commensurate with that produced.

Another suggestion that has been made and practiced to a limited extent is to mingle the fine ore with low-grade matte or rich copper slag, in such quantity as will be absorbed, with or without solidification of the absorbing medium. This process gives a semi-fused mass suitable for smelting if slag

has been used, or for converting in the case of matte. In either event the fine ore shortly becomes part of a molten bath with no chance for escape as dust.

The most recent and novel of the means proposed is to be used at Cananea for avoiding loss in the treatment of Miami copper concentrate. This material is very fine and high grade. Ordinary methods of smelting would result in high losses and hence some scheme had to be adopted to increase metallurgical recovery. It is proposed to blow the fine concentrate trough the tuyères directly into converters charged with matte and thus cause it to become a part of the molten bath. This will eliminate dust loss and will lower the smelting cost materially.

Expenditures at the Gary Steel Plant.

Four months ago we made some editorial remarks upon "the iron industry's insatiate thirst for capital," and the annual report of the United States Steel Corporation gives figures of its expenditures at its new plant at Gary, Ind., which furnish a concrete illustration of the principle adverted to. The expenditures at Gary would make the iron and steel engineer of half a generation ago stand aghast. To Jan. 1, 1911, they amounted to $69,978,695, of which $16,072,851 was spent in 1910. For work authorized at Gary, but still to be completed, there was the additional sum of $15,500,000, making in round figures a total of $85,000,000 expended, or to be expended, at Gary in connection with the present plans. This expenditure covers the land for both the plant and the town (less credits for lands, lots and houses sold), buildings and other town improvements, an enormous amount of terminal railroad work, as well as the moving of two trunk-line railways, lake harbor and docks, by-product coke ovens, 12 blast furnaces, 42 open-hearth steel furnaces and various rolling and finishing equipment.

There has been appropriated from surplus net income a total of $65,000,000 for Gary, of which $10,000,000 was appropriated in 1910; in addition to this construction work aggregating $9,775,506 was financed by three subsidiary companies, the American Sheet & Tin Plate Company, the American Bridge Company and the Chicago, Lake Shore & Eastern Railway Company, which have been doing construction work at Gary. Thus there is left, of the $85,000,000 expenditure authorized, a trifle over $10,000,000 to be provided, either by future appropriations from surplus earnings, or by subsidiary company financing.

The production of the Gary plant in 1910 was as follows, in gross tons:

Pig iron	729,072
Steel ingots	1,006,252
Rails	435,142
Shapes, bars, etc.	340,993
Total rolled steel	776,135

The blast furnaces are rated nominally at 150,000 tons annually, or 1,200,000 tons for the eight, and the finished rolled steel, when the works are running full, may be estimated at approximately the same total. Thus we see that for 1,200,000 tons of finished steel approximately half of it rails, there is involved an expenditure of $85,000,000, or $72 per ton of annual output, and this does not include coal or ore mines or transportation facilities other than docks and terminal railroad work. Of course, a portion of this may be written off, because town lots or buildings will be sold, or the buildings will furnish revenue, but as the total expenditures in the town, less credits for lands, lots and houses sold, have amounted only to $10,509,325, the expenditures for the plant proper cannot be set at less than $75,000,000, which means $62.50 per ton of annual product.

This allotment per ton of output is very large compared with the standards of half a generation ago, when expenditures ran from $10 to $20 per ton, but it is small compared with the profits which ought to be realized, for 10 per cent to cover interest and depression would involve only $6.25 per ton. Depreciation in the steel industry is written chiefly by what occurs outside the plant, not by what occurs inside; in other words, by the progress of the industry. As the Gary plant is intended to be far ahead of anything yet attempted its depreciation may rightly be estimated as low for the next few years.

The Electrode Problem.

In any electrochemical process, be it electrolytic, electrothermic or a combination of the two, the cost of power is often a very large single item in the cost sheet. Among the other items, such as labor, repairs and renewals, interest and depreciation and general expenses, the second named includes a figure often large and usually uncertain, viz.: The cost of replacement of electrodes. The cost of power, on the other hand, is always large but rarely uncertain. Now in any new business undertaking uncertainty is usually the greatest deterrent. Indeed, the largest fortunes of this country have been gathered for the most part by men whose boldness is founded on the ability to see further and clearer through the haze than can the ordinary man. Darkness generates fear, but the light of day generates courage.

Accordingly, any light that can be shed on the commercial engineering of electrodes is of advantage to the wide and growing circle of metallurgists who are concerned with electrolytic and electric-furnace processes. The former are as a class older than the latter and hence have the advantage of the latter in the question of electrodes. For, in a properly developed electrolytic process, the cost of electrodes is not startling, varying, as it does, from 3 per cent to 10 per cent of the total cost. In the newer and wider field of the commercial electric furnace, especially where the electric furnace is operating on smelting processes or on refining, the cost of electrodes is sometimes as high as 25 per cent of the total cost of treatment of the successful process. And in the case of the unsuccessful process the cost of electrode renewals is so unexpectedly great as to cause often the abandonment of attempts that seemed at the first very hopeful.

Undoubtedly, great progress has been made in the past ten years in the manufacture of electrodes and also in the design of electrodes for their peculiar functions. We are confident that the next five years will witness even greater progress. The process of manufacturing electrodes is everywhere essentially the same. Briefly described, some form of carbonaceous material such as crushed "oil-coke" is mixed with tar and the mixture molded hot to the required form; the molded article

is then subjected to slowly increasing temperature until the tar is either volatilized or carbonized; thereby the solid particles of the original carbon are cemented together in a more or less compact mass; finally, the baked electrodes are annealed by slow cooling.

This process seems quite simple. In point of fact it is both simple and elementary, for a very satisfactory home-made electrode can be made for an intermittent type of electric furnace "in place," by tamping a hot mixture of tar, broken electrodes, and crushed coke in a form, "larding" it with a modern woman's hatpin, driving off the tar slowly with a wood fire and completing the cementing carbonization by auto-generated electric heat. But the process of making regular molded electrodes for a continuous electric furnace is not so simple as it looks at first glance.

In the first place, the chemical and physical properties of both the carbon and the binder are never uniform. Every chemist knows what a complex stuff tar is and also the varying idiosyncrasies of the carbon molecule. Next, to make a compact mass, the structure must have a certain density and at the same time a certain porosity. It seems like a paradox to combine these two diametrically opposed qualities in one article. But, nevertheless, it must be done. To insure firmness, the particles of carbon must be bonded well together, for otherwise the electrode obviously will be mechanically weak. If, on the other hand, the structure be very dense, the evolution of hydrocarbon gases in the baking will cause the development of many small places of intense local pressure with ensuing "checking" and resultant formation of planes of weakness in the finished article. In the third place, the baking must be done exceedingly slowly to reduce the internal pressure of hydrocarbon gases generated to such an extent that they can percolate through the electrode and get out without damaging the electrode. We see plainly that the whole operation is one that needs as much care and conscience as nursing a baby.

Now as the modern tendency is to build electric furnaces of great power requirements, the diameter of the electrodes asked for is, of course, greatly increased. It is apparent that with conditions such as they are the difficulties of manufacture are tremendously increased as the size of the electrode is increased. Carbons for arc lamps are not hard to make. In this case it is largely a question of cheapness gained by a large output. But to produce an electrode 24 in. in diameter and 120 in. in length is a triumph of mechanical and chemical engineering.

As is well known, we use in this country both graphitized and amorphous carbon electrodes. Each has its peculiar advantages and each has its peculiar disadvantages. Both are fairly resistant to the slightly oxidizing influences of the nearly neutral atmosphere of the average electric furnace. The graphitized article costs considerably more than the amorphous carbon electrode but it is a much better conductor of electricity. On the other hand, it is a better conductor of heat. The significance of these two facts has been discussed at such length in this journal a year ago in connection with the laws of electrode losses that there is no necessity to discuss this matter again at the present time. The graphitized electrode can be machined and so a composite electrode can be made, as is done at South Chicago and at Worcester. This is practically denied its rival. Both can be fashioned so that a new electrode can be "butt-connected" to the stub end of an old electrode and so the electrode is for all practical purposes fed, as needed, continuously into the furnace. The greatest point of superiority of the graphite electrode is usually unnoticed. This is its great power of resistance to sudden temperature changes. In the electric furnace industry, especially as developed in the United States, the workmen have never the skill in the art at first that is needed and developed later. The natural result is uneven working and its concomitant, bad temperature control. This affects the amorphous carbon electrode severely and the result is a high proportion of electrode scrap, even when the carbon electrodes have been made under good conditions.

It would appear that the process of baking the electrodes in electric furnaces of the Acheson type is inherently superior to the operation as conducted in the open-hearth furnace with its removable top and the covering of sand over the molded electrodes. The flow of heat from the innumerable points of local resistance is much more uniform in this style of electric furnace than in the gas-fired furnace, where the heat flows down through the sand covering to the entire mass of electrodes. As in a roasting furnace, the question of surface is of most importance. In the Acheson electric furnace the heat is generated in proximity to the place it is needed.

To cheapen the cost of production, it might be well to consider the manufacture of electrodes built up of standard elements of say 3 in. x 8 in. x 72 in. These elements could be produced far cheaper than the larger dimensioned electrodes. Practical experience seems to show that the built-up electrode fills the bill. The elements could be produced cheaply because the heat would only have to penetrate 1½ in. and the hydrocarbons would have just this short distance to percolate outward.

It may also be well to consider a very slow and careful annealing when once the maximum temperature has been reached. A slow annealing greatly toughens the carbon and a slow adjustment of the internal strains makes for the desired quality of resistance to sudden temperature changes—a condition of the American climate that even affects the atmosphere of the American electric furnace.

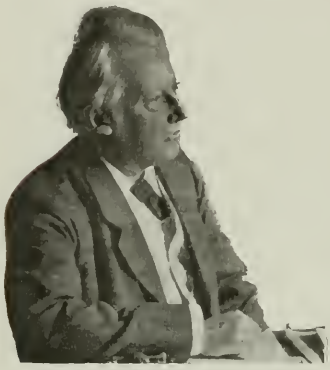
Undoubtedly some of the large concerns using electrodes in quantity will in the future make their electrodes in their own plants. Ground "butts" and ground scrap electrodes are suitable ingredients of the mix and cheapen the cost of manufacture. A very profitable field of study is the application of the microscope to the microstructure of electrodes. The methods of attack in research which have developed the special sciences, known as metallography and petrography, could be well used to garner some solid scientific facts about electrode manufacture.

Indeed, the broad field of electric furnaces, their necessaries and accessories, such as voltage-regulators, pyrometers, refractories, and electrodes, is at the present outlook an ever-expanding one and in it progress is demanded. As the use of the electric furnace increases "the essential details" become better developed and easier of application. The smaller and apparently insignificant points of electrode manufacture which have been pointed out above, when incorporated in the "skill of the art," will render much easier the fruition of many electric-furnace processes.

The Death of Professor van't Hoff.

We regret to report the death of Professor J. H. van't Hoff on March 1, at Steglitz, near Berlin, Germany, at the age of 59 years. Professor van't Hoff was taken ill during the autumn of 1906 with pleurisy, which turned into tuberculosis, and he had not been well since. During the summer of 1907 he was critically ill for three months, but partially recovered, never, however, throwing off the insidious disease.

Jacobus Henricus van't Hoff was born in 1852 at Rotterdam, Holland, as the son of a physician, and was educated in the public school of that city. In 1869 he entered the Polytechnicum (Institute of Technology) at Delft and in 1871 the University of Leyden; subsequently he studied at the Universities of Bonn, under Kekule; of Paris, under Wurtz, and of Utrecht, where he received the degree of doctor of philosophy in 1874 and where he began teaching in 1876. He was called to Amsterdam in 1877, where he was soon made a professor. In 1894 he was called as professor of physical chemistry to the University of Berlin.



J. H. van't Hoff

Professor van't Hoff's name will be connected forever with the history of modern physical chemistry, which owes to him directly some of the most fruitful and important broad generalizations and indirectly the impetus to an enormous amount of experimental work. "Wenn die Könige baun, haben die Kärrner zu thun."

In 1874, while still a student at Utrecht, he published his paper on the necessity of representing structural chemical formulas in a space of three dimensions, instead of a plane of two dimensions, and on the application of this new stereochemical method to the explanation of optical isomerism.

Van't Hoff's most important contributions to science, however, were made in two publications, issued in Amsterdam in 1884 and 1885 under the title "Etudes de Dynamique Chimique" and "Lois de l'Equilibre Chimique dens l'Etat Dilué, Gaseux ou Dissous." In these two papers those broad generalizations are contained which were so effective in determining the future course of the development of physical chemistry. First, van't Hoff's "principe de l'équilibre mobile" which replaced Berthelot's "principe du travail maximum." According to van't Hoff, when two chemical systems (represented by the two sides of a chemical equilibrium equation) are in equilibrium at a certain temperature, then a rise of temperature causes a shifting of the equilibrium toward that system (or toward that side of the equation of equilibrium) the formation of which is combined with absorption of heat.

Further, van't Hoff showed here how we have in the electrical energy of a galvanic cell a measure of the chemical affinity of the reactions taking place in the cell.

But perhaps most important of all was the generalization by which van't Hoff developed the parallelism between dilute solutions and gases. The laws for the osmotic pressure in dilute solutions and for the gas pressure in gases are identical. How the apparent discrepancies of this new rule from the facts in the case of electrolytes led directly to the electrolytic dissociation theory is too well known to be further recorded here.

Van't Hoff later took up the study of solid solutions, and the depth of his scientific imagination is indicated by his applications of physical chemistry to geology. In this connection his patient work on double salts concerning the Strassfurt salt beds must be mentioned, to which he devoted the last ten years of his life.

Program of New York Meeting of American Electrochemical Society.

The first convention of a national society to be held in the new Chemists' Building at 50-54 East 41st street, New York, is that of the American Electrochemical Society, the dates being April 6 to 8 (Thursday to Saturday).

There will be professional sessions for the reading and discussion of papers on the three mornings. All will be held in the Chemists' Club. The Friday and Saturday sessions will start at 9:30, the Thursday session at 10 o'clock, when the annual business meeting will be held. At a special evening session on Friday the retiring president, Professor W. H. Walker, will present his address.

For the afternoons the following **excursions** have been arranged: On *Thursday* afternoon the Laurel Hill works of the Nicholas Copper Company in Brooklyn will be visited, which is the largest copper refinery in the world.

On *Friday* afternoon the following optional visits have been arranged: (1) The new and splendidly equipped plant of the Hanson & Van Winkle Company in Newark, manufacturers of electroplating material and machinery, with a thoroughly modern demonstrating electroplating plant; or (2) electric furnace laboratory of Dr. F. J. Maywald and the photoengraving and electrotyping shops of the Moss Engraving Company in New York City; or (3) New York Electrical Testing Laboratories, the Chemical Laboratory of the College of New York and the Laboratories of Columbia University.

On *Saturday* afternoon an excursion will be made to the Perth Amboy plant of the American Smelting & Refining Company. It comprises ore smelters, lead refining plant, electrolytic copper refining, electrolytic silver refining and the bessemerizing of leady copper matter in basic-lined converters. This immense plant refines, per month, 7,500 tons of copper, 8,000 tons of lead, 3,000,000 ounces of silver and 20,000 ounces of gold. In doing this it smelts 15,000 tons of ore and bessemerizes 1500 tons of leady copper matter. Attention is particularly directed to the basic-lined converters, the latest improvements in the metallurgy of copper.

Social Functions.—On Thursday evening a subscription dinner will be held at the Chemists' Club. On the evening of Saturday, April 8, the New York section of the American Electrochemical Society tenders an invitation smoker to the visiting members and guests of the society and to the Chemists' Club.

The program of **papers** is as follows:

Thursday morning after the annual business session, which begins at 10 o'clock.

Report of the Committee on Standard Tests for Dry Cells: C. F. Burgess.

The Testing of Dry Cells: W. B. Pretz.

Electrically Fused Alumina as a Refractory: L. E. Saunders.

A New Electric Resistance Furnace: F. A. J. Fitzgerald.

A New Laboratory Electric Furnace: M. M. Kohn.

An Electric Furnace for Heating Bars and Billets: Thaddeus F. Baily.

The Johnson Electric Zinc Furnace: J. W. Richards.

The Condensation of Zinc from Electric Furnaces: F. T. Snyder.

Reliability of Electric Furnaces for Commercial Work: F. T. Snyder.

Friday morning, 9:30.

Electric Cyanamide Process for Gold Ores: J. F. Clancy.

The Electrolytic System of Amalgamating Gold Ores: E. E. Carey.

The Electrolytic Corrosion of Electroplated Objects: W. S. Landis.

Electrolytic Refining as a Step in the Production of Steel: C. F. Burgess.

Some Problems of the Electroplater: G. B. Hogaboom.

The Haas-Oettel Electrolytic Cell: E. E. Niswonger.

Electrical Heating for Preventing Superheating of Liquids: J. Howard Mathews.

A Mercurous Perchlorate Coulometer—Preliminary Experiments: F. C. Mathers.

Some Observations on the Laboratory Production of Aluminum: H. K. Richardson.

Exhibition of the Schoenherr Arc for Fixatives of Atmospheric Nitrogen: J. W. Turrentine.

Electric Discharges in Gases: L. A. Parsons.

The Mechanism of Electrolytic Transfer: J. W. Richards.

Polarization in Its Relation to the Decomposition Pressure of Electrolytes: O. P. Watts.

Friday evening, 8:15. Joint meeting with the New York section of the American Chemical Society.

Presidential Address: Dr. W. H. Walker.

Lecture by Dr. Harrison E. Patten on "The Relation of Surface Tension and Electrochemical Action."

Saturday morning, 9:30.

Electric Furnaces for the Manufacture of Steel: James Lyman.

Some Experiences with the Electric Furnace at South Chicago: C. G. Osborne.

Electric Steel Processes as Competitors of the Bessemer and Open Hearth: A. E. Greene.

Design of a Fifty-Ton Induction Electric Steel Furnace: A. Hiorth.

A New Type of Electric Furnace: Carl Hering.

Electric Furnace Treatment of Nickel Ore: W. L. Morrison.

An Electrolytic Furnace Method for Producing the Rare Metals: J. W. Beckman.

The Advantages of Keokuk, Iowa, for Electrochemical Industries: F. P. H. Knight.

The Advantages of Maine for Electrochemical Industries: C. Vey Holman.

The Western Metallurgical Field.

Magnetic Roasting.

The treatment of those Western ores which contain a mixture of iron and zinc sulphides, pyrite and blende is in a large measure dependent on magnetic roasting and separation. The magnetic roast is a delicate operation and the devices used for producing it are not always sufficiently under the control of the operator to turn out a uniform product. Overroasting produces oxide of iron, which frequently is seen in roasted ore as a reddish substance, and which reduces the efficiency of the subsequent magnetic separation.

The magnetic roast usually is produced in furnaces not unlike those used for desulphurizing roasting. They have certain inherent drawbacks which, in a measure, make them unfit, or at least not the best, for magnetic work. As a rule the ore is exposed to heat for too long a time, and all of the particles are not evenly exposed, so that a variable product results. By rabbling a deep bed of fine ore on a hearth one cannot be certain that all particles receive the same degree of heat for the same time, although the purpose of the rabbling is to accomplish this result as well as to advance the ore through the furnace.

A new idea in magnetic roasting has been applied by Mr. A. R. Wilfley, known for his invention of the concentrating table of that name. Mr. Wilfley has tried to evolve a furnace that would give to all ore particles as nearly the same treatment as it is possible to do in a commercial roasting furnace. The furnace consists of a circular, rotating roasting hearth, with an auxiliary fire box, feeding device and means for removing the ore from the hearth when roasted. By an adaptation of the roller feed, such as is used on some magnetic and electrostatic separators, the ore is fed onto the hearth in a very shallow bed, approximately one grain deep. The hearth rotates in the opposite direction to the path of the hot-furnace gases, so that the ore gradually advances through an atmosphere of increasing temperature until it is finally removed from the hearth after one revolution. The points of feed and removal of the ore are in close proximity between the inlet and outlet of the furnace gases. The device for removing the ore from the hearth is a specially constructed suction nozzle, which is connected with a suitable receptacle.

A number of advantages will be apparent in this construction. There will be little tendency for the ore particles to become agglomerated; one particle will have the same treatment as another; the rate of speed of the hearth can be regulated to give exactly the right time of exposure according to the temperature and the roast is immediately arrested when the ore is cooled in the suction nozzle. Naturally the time of exposure of the ore to heat is very short, one to three minutes sufficing to produce the same result that is accomplished in an ordinary roaster in the same number of hours. The capacity of an experimental machine has shown that 7.5 sq. ft. of hearth area per minute will give a magnetic roast to one ton of ore in 24 hours.

Legislation.

This is the biennial period when Western Legislatures consider, among other things, ways and means to control the metallurgical and mining industries in the interest of the producer of ore, as well as methods for obtaining more State revenue from both industries. Two Colorado bills show the trend of legislation this year. Their subject matter is not exactly new and it is doubtful if either of them will pass, but they are interesting as reflecting the attitude of legislators.

The Joyce bill for regulating metallurgical plants seeks to prevent the imposition of unjust or unreasonable rates on ore treatment, the giving or receiving of rebates, or any other form of discrimination, and empowers the State commissioner of mines to enforce the provisions of the bill. Some years ago when the smelting of ores was the foremost metallurgical industry in Colorado there was considerable complaint against the smelter monopoly on account of treatment rates. It was alleged that large shippers were favored at the expense of the small, and that no uniform tariff existed for all shippers of the same kind of ore. The difficulty then, as now, was to make workable provisions for enforcing regulation of the industry.

The Joyce bill seeks to empower the State commissioner of mines to enforce the provisions of the bill, but such a thing would be almost impossible, even if conditions urgently demanded rate regulation. Any corporation strong enough to control the metallurgical situation would, under our present system of politics, first see that an acceptable commissioner of mines was appointed, after which the provisions of the law would be of little effect.

The McPolin bill for the regulation of the practice of assaying, and requiring the registration and examination of all assayers in the State, embodies another idea that frequently has been put forward. It undoubtedly springs from the abuses that have been perpetrated in the name of assaying by men who have taken advantage of a respectable calling to engage in criminal practices. Every rich mining camp in the West has had to fight the "high graders" who run alleged assay offices and buy small lots of stolen high-grade ore. In the absence of adequate means of coping with them the leading companies frequently have taken matters in their own hands

and have forcibly stopped the practice of the high-graders.

The proposed bill for the licensing of assayers is apparently another step in the elimination of the high grader as well as the incompetent workman. As with most bills of good intent the carrying out of its provisions might prove difficult. The greatest care would have to be exercised in the selection of the proposed board of examiners, for they have the power to accept or reject applicants, to supervise their work in practice and revoke licenses in case of unprofessional conduct or incompetency.

The bill would have several beneficial effects if passed and properly enforced. The public would be protected from unscrupulous assayers who sometimes falsify reports for financial considerations. Legitimate assayers would be accepted by the public on the face of their standing with the board of examiners.

No hardship would thereby be worked, and as all assayers in metal mining districts are engaged in the same line of work there would not be the objection to licensing them which is quoted against the licensing of civil engineers, for example, in which profession all members are not engaged in the same class of work and ought not to be required to show proficiency in all branches of the profession.

Utah.

A sequel to the smoke suits brought by the farmers of the Salt Lake Valley against the local smelters several years ago is the recent decision of the Bingham Mines Company, owner of the old Bingham Consolidated Smelter, to raze that plant and dispose of the equipment. This smelter was put in operation in 1901 and operated successfully until the close of 1907, when it was closed by order of the court on account of the damages caused by its fumes to surrounding agricultural land. The plant was well equipped, having five blast furnaces, one reverberatory, four McDougall roasters and the complementary converting department. When the plant was closed there were plans on foot to enlarge and improve it, but these were abandoned and the closing of the plant followed.

A recent transaction of importance was the leasing of the Ontario property at Park City, Utah, to Salt Lake men. For two years past Mr. Henry M. Crowther has represented a company which has been experimenting on the old stope fillings of the Ontario, ascertaining their value and amenability to modern methods of metallurgy. Originally the Ontario produced very rich ore which was treated by the Russell process. The average grade was over $100 per ton, and the low-grade ore was used as filling.

It is said that there are about 1,000,000 tons of this material, and it is the intention of the leasing company to remove and treat it.

The experimental work has shown that the methods of fine grinding, agitating in cyanide solution, filter pressing and precipitating by zinc dust developed in recent years will permit an extraction of over 95 per cent of the gold and about 80 per cent of the silver. With such an installation in a remodeled mill it is expected that 300 tons of ore will be treated daily. The improvements will cost in the neighborhood of $200,000.

The New Copper Mills.

The first unit of the large Ray Consolidated mill in Arizona has been put in operation and from this time on the company will be classed among the producers. The Miami also is expected to be in operation by the time this report reaches our readers.

The Chino mill in New Mexico is not expected to be in operation until July, but when it commences it will have 30 years' ore supply at the present rated capacity of the mill. The latest reports from Chino state that 45,000,000 tons of copper ore have been developed, and that 70 per cent of this will be mined by steam shovel.

The Non-Ferrous Metal Market.

The general improvement in the spelter market and the decline in prices for spot tin have been the principal features of the metal market since our last report. In copper and lead the volume of business is fair, but only for immediate needs of manufacturers.

Copper.—The March market has been without special feature, both domestic and foreign demands being light. It is generally understood that the largest transactions were at concessions in price, as the sellers seemed eager to get business. Lake copper is quoted at 12⅜ to 12⅝ cents and electrolytic at 12.15 to 12.20.

Lead.—No improvement has been noted in this market, despite the expectation that the usual demand would occur with the coming of spring. Considerable Missouri lead has been sold and the St. Louis market has dropped to 4.22½ to 4.25 cents. The New York market quotes 4.37½ to 4.40 cents.

Spelter.—Improvement in the galvanizing trade has stimulated the spelter market somewhat, with the result that prices are a little higher than last month. St. Louis spelter is quoted at 5.45 to 5.50 and the New York market at 5.60 to 5.65 cents.

Tin.—The quotations on this metal have been erratic during March. In the beginning of the month the metal was expected to show advances owing to the operations of the syndicate which was supposed to have taken advantage of the weakness developed in February. Foreign markets showed a steady decline, however, and the domestic corner was broken. Future tin has held its own and spot has suffered the decline. March tin was quoted at about 40⅜ cents.

The Iron and Steel Market.

March showed a definite decline in the rate of buying of finished steel products, which had increased so rapidly late in January and early in February. The decrease is not traceable altogether to a decrease in general business activity, although it does appear that general business is hardly as active as it was early in the year. Nor is it traceable to the famous rate decisions of the Interstate Commerce Commission, made Feb. 22. It appears rather that during December and the fore part of January a considerable tonnage of requirements backed up, partly because buyers at that time were fearful of a decline in the market, and partly because they wished to avoid incurring obligations or increasing stocks until after the inventory date. The release of this business, at a time when requirements were increasing, effected a rapid increase in the rate of booking orders. To use figures for conciseness rather than precise accuracy, bookings of orders for finished steel products averaged 35 to 40 per cent of capacity in December and the early part of January, 75 to 85 per cent late in January and in February and 55 to 65 per cent during March.

The iron and steel trade regarded rather seriously the claims made by the railroads during the pendency of the rate cases before the Interstate Commerce Commission that an adverse decision would greatly curtail their buying power, and was disappointed at the decisions rendered. However, no direct results have been traced. No orders for railroad material have been canceled, or enquiries withdrawn, while along certain lines there seems to have been a slight increase in the volume of railroad buying. In the last analysis, there is good reason to expect the throttling of the rate advancing tendency to prove favorable to the iron industry. The railroads had reached a point where large extensions were very improbable. Their existing equipment seems to be fairly adequate to the conduct of the business offered, and large consumption of iron and steel for extensions to facilities was not to be expected. On the other hand, the railroads have reached a point where they are wearing out material very rapidly, their ton-mileage of freight having doubled every 10 or 12 years. The replacement of worn-

out material, whether in brake shoes, entire cars, or rails, does not involve fresh borrowing of capital, being an ordinary item of expense, and whatever tends to increase the volume of traffic, as the curbing of the rate advancing tendency does, makes for more wearing out of material and more demand along the only line in which any large demand was to have been expected.

While bookings in the finished steel trade decreased somewhat in March, production increased. It required time for the mills to limber up and the heavy bookings in February resulted in heavy operations in March. The mills ran at about 50 per cent of capacity in December and January, about 60 per cent in February and about 75 per cent in March. It is evident that they will not be able to maintain the present pace of production unless there is an increase in buying. This is to be expected as spring weather comes.

There is no disposition to buy ahead, and current orders are for current requirements. By far the bulk of the bookings in March were in the form of specifications against old contracts, there being relatively little strictly new buying.

Prices of finished steel products are being held by the mills all along the line, there being apparently a firm conviction that at least as large a tonnage of business will result from present prices as would be brought out by lower prices, and there is evidently also a firm conviction that any departures from existing prices by individual producers would quickly inaugurate a general reduction, in which the original cutters would suffer as much as their neighbors.

Effective at the opening of business Monday, March 6, wire products were advanced $1 per ton, this following an advance of a dollar a ton made effective Jan. 23. The mills are adhering strictly to the advanced prices, but the same cannot be said of jobbers, who are cutting the market more or less generally by a dollar a ton. They did a little cutting following the first advance, and the practice is now more general. The trade custom is to book jobbers with contracts prior to an advance, these contracts being good for specifications during the ensuing 60 days. After the first advance jobbers specified liberally on their old contracts, but retailers and large consumers did not take hold in like manner, with the result that jobbers were left with large stocks, and at the moment they are buying rather sparingly.

On March 10 the United States Steel Corporation reported its unfilled orders at the close of business Feb. 28 at 3,400,543 tons, representing a gain of 289,624 tons during February, against a gain of 436,162 tons in January, and a continued loss during 1910 aggregating 3,252,274 tons for the year.

Pig Iron.

The total turnover in pig iron in March was perhaps a trifle larger than in February, that month having shown a good gain over December or January. There was a barely perceptible tendency toward higher prices in March. At Buffalo and Cleveland the asking prices of furnaces were advanced about 25 cents, but only after considerable sales had been made at the low point. In eastern Pennsylvania a sharp rise occurred in basic iron, from $14.50 to $15.25, delivered Philadelphia. In the South the $11, Birmingham, basis was simply maintained, with $11.25 to $11.50 demanded for deliveries after July 1. In the valley market nothing of interest occurred except the development of a price on foundry iron for delivery over the second half, at 25 cents advance over the prompt and second quarter market. Basic iron was practically dormant, the sales noted in last report seeming to have filled consumers' requirements. Bessemer moved in small lots at the regular price. We quote at valley furnaces, 90 cents higher delivered Pittsburgh: Bessemer, $15; basic, $13.75 to $14; No. 2 foundry, $14 to $14.25; malleable, $13.75.

Steel.

Shipments of semi-finished steel in March showed a large increase over February, but almost entirely by reason of heavier specifications on existing contracts, there being very little fresh buying. Bessemer and open-hearth billets remain quotable at $23, Pittsburgh or Youngstown, and sheet bars at $24. Several of the wire mills advanced their price on rods from $29 to $30 at the time of the advance in wire products, but it seems probable that material can be picked up at the old figure.

Finished Steel.

Finished steel prices are held firmly all along the line, with the exception of shading on wire products by some jobbers ,as already noted. Prices f. o. b. Pittsburgh, except where otherwise noted, are as follows:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill except Colorado.

Plates, 1.40 cents for tank quality.

Shapes, 1.40 cents for beams and channels, 3 in. to 15 in. inclusive, zees and angles, 2 x 3 and larger.

Steel bars, 1.40 cents, base; iron bars, 1.35 cents, Pittsburgh; 1.25 cents, Chicago.

Wire nails, $1.80, base, per keg; plain wire, 1.60 cents, base; galvanized barb wire, 2.10 cents; painted barb wire, 1.80 cents.

Black sheets, 28 gage, 2.20 cents; galvanized, 3.20 cents; blue annealed, 10 gage, 1.65 cents; painted corrugated roofing, $1.55 per square; galvanized, $2.75.

International Congress of Applied Chemistry, 1912

A preliminary announcement has just been issued giving the present status of the organization of the congress to be held in this country from Sept. 4 to 13, 1912.

This same announcement contains tentative rules on the publication of papers and on sectional procedure and the suggestion of a special interests' registration bureau. As these are matters of greatest immediate importance, they are given here slightly abbreviated. We will be glad to place our correspondence columns at the disposal of our readers for discussion and criticism. These tentative rules should be made final as soon as possible, but before this is done they should be clearly understood and discussed.

Tentative Rules Governing the Receipt of Papers for Presentation or Publication.

All papers should be in the hands of the American committee on or before July 1, 1912. All such papers should be presented in *duplicate,* legibly written, but preferably typewritten. *Each paper must be accompanied by an abstract* thereof also in duplicate, legibly written, but preferably typewritten.

All papers received prior to July 1, 1912, and accepted for publication will be printed prior to the meeting of the congress and grouped according to the sections to which they are assigned; papers received after July 1, 1912, and accepted for publication will be printed prior to the meeting of the congress if practicable, but it cannot be guaranteed that they will be placed in the section to which they belong, but they may appear in an appendix.

The American committee will neither revise nor edit any papers or abstracts; papers received for publication will be printed *in extenso* as offered, or only the abstract accompanying the full paper will be printed, or the paper will be printed by title only, together with the name and post-office address of its author, or the paper will not be printed at all, as may be decided in each case by the committee on papers and publications.

Authors will not receive printer's proofs of papers or abstracts; authors must do their proofreading on the manuscript; whatever is printed by the American committee will be printed in exact accordance with whichever of the authors' manuscripts is selected for publication.

Discussions will be recorded in the official language in which they are uttered, and participants in the discussions will have an opportunity of editing the manuscript report of such discussion; the American committees will print from such edited

manuscript report of the discussion, and printer's proofs will not be sent to participants.

No paper which has previously been published shall be read at the eighth congress nor printed in its final report without the consent of the sectional executive committee, the committee on papers and publications and the executive committees of the eighth congress having first been obtained.

The American committee will proceed to print the papers during the first half of July, 1912. The size of the edition printed will be determined by the number of membership fees received on or before July 1, 1912.

Persons contemplating membership in the congress should have their membership completed prior to July 1, 1912, in order that they may be sure of receiving a copy of the report of the congress. Membership fees can be received after July 1, 1912, only as subject to the condition that copies of the report of the congress cannot be guaranteed and will be supplied only until the number of extra copies printed is exhausted.

Tentative Rules on Sectional Procedure.

The presentation of the subject matter of any paper before any section or subsection shall not exceed ten minutes; if the original paper requires more than ten minutes for reading, it must be suitably condensed.

All participants in discussions must speak from the rostrum and not from the floor of the house; where practicable, discussions should be handed in to the sectional secretary in writing and in advance.

Discussion is limited to five minutes for each participant unless consent of those in attendance be obtained for an extension of that time.

According to the proposed order of business, the reading of minutes of the preceeding meeting is to be omitted except in so far as they may contain resolutions or motions calling for action by the section or subsection at that meeting.

After the reading of the minutes, if any be read, the order of the day shall be taken up.

The sessions of sections and subsections will begin at 10 in the forenoon and last until 12 noon; the afternooon sessions will begin at 2 and close at 4 o'clock, except on those afternoons on which there shall be public or general lectures, when the afternoon sessions will begin at 1 o'clock and end at 3. Any papers on the order of the day not reached during the session to which they are allotted will be taken up at the meeting next succeeding in which the order of the day is completed prior to the hour of adjournment, and not otherwise. No paper is to be taken up for presentation within 15 minutes of the adjournment hour, except by unanimous vote of all members present.

Special Interests Registration Bureau.

It is proposed to establish at the eighth congress a *Special Interests Registration Bureau.* This will be distinct from the Central Registration Bureau. Members concerned with any one of the very special phases of chemical industry, and prepared to exchange information with their professional brethren, may register under such specialties. The list of registrants in each specialty will be made accessible to all, either in a pamphlet printed and distributed daily or by exhibiting copies of the typewritten list on bulletin boards. Is such a Special Interests Registration Bureau desirable? If such a special registration is established, what are the titles of the different special phases which should appear at the head of such registration lists in order to be sure of meeting reasonable demands for a minutely specialized classification of chemical interests?

These two questions should be discussed and answered by chemical and allied societies as well as by individual chemists in order to enable the American committee to decide the advisability of such a bureau.

The opening meeting of the congress will be held at Washington, D. C., on September 4, 1912. The other meetings, business and scientific, will all be held in New York. This will begin on Friday, September 6, 1912, and will end on Friday, September 13, 1912. The president of the United States is the patron of the congress, Dr. E. W. Morley the honorary president, Dr. W. H. Nichols the president.

Dr. B. C. Hesse, 25 Broad Street, New York City, is the secretary of the congress.

CORRESPONDENCE

Separation of Oxygen by Cold.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In the January issue of your journal there is an article with the above title which constituted the address of Mr. James Swinburne before the Faraday Society in London.

We are accustomed to receive as gospel in the scientific world anything which bears the hall mark of the Faraday Society, but some of the statements in that paper are so at variance with other statements made before equally august bodies of scientists that it seems worth while to call attention to the discrepancies to the end that the truth may be brought out more clearly and definitely.

One of the statements which constitutes a discrepancy from the accepted facts involves a purely theoretical consideration—the other a purely practical one. The former is contained in the sentence:

"The mixture of two mutually inert gases thus involves increase of entropy. . . . As this depends solely on the logarithms of the free paths it depends in the case of two gases at the same temperature and pressure only on the relative volumes of the gases before they are mixed."

The immortal Clausius invented entropy in the broadest sense—that is, he discovered the function and took the name from the Greek. His definition was, roughly, that the change in entropy of a given body between two temperatures was the integral of the infinitesimal quantities of heat passing at each temperature divided by that temperature. The whole of thermo-dynamics is founded on this definition. There may be mathematical laws which give a relation between the entropy of a gas and the length of the free path of its molecules, but it is not evident to this deponent how there can be any increase in entropy by mixing volumes of different gases at the same temperature and pressure. It would seem, in fact, that it were demonstrable that this were a mathematical impossibility.

If your journal is to give the weight of its countenance to articles containing statements so at variance with commonly accepted physical definitions it owes to its readers some explanation of the differences, or a disclaimer of responsibility for the ideas set forth.

The other discrepancy involves a difference in absolute facts between the statements of Mr. Swinburne and those made by M. L. Marchis before the International Congress of Refrigerative Industries, held, I think, in Paris in 1909. The title of M. Marchis' paper is "The Production of Low Temperature and Refrigeration." It is republished in the report of the Smithsonian Institution for 1910, recently issued. All the articles republished in this report are taken from the very highest authorities and publication therein implies the approval of one of the leading scientific bodies of America.

On the subject of separating oxygen from nitrogen Mr. Swinburne declares that to produce a ton (of oxygen) would need 120,000 kw-hours. This result he reaches by a theoretical reasoning which the present writer is unfortunately incapable of understanding, but the statement is clear and distinct.

On the other hand, M. Marchis states that the Société L'Air Liquide has built apparatus which actually do deliver 100 cu. m of pure oxygen per hour, and that these apparatus yield 1.19 cu. m of pure oxygen per hp-hour, or 3.67 lb. If Mr. Swinburne were using the English ton of 2240 lb., 3.67 lb. would go into this 610 times, and, therefore, to produce one ton of oxygen would require 610 hp-hours, or 455 kw-hours.

This is about 1/300 part of the power declared by Mr. Swinburne to be necessary for this operation.

The writer personally has a letter from the Société L'Air Liquide in which they offer to furnish an apparatus which will deliver 500 cu. m of pure oxygen per hour, of 1545 lb., with only the power required to compress 2500 cu. m of air per hour to a pressure of 10 atmospheres. The power required for this operation in a good compressor would not exceed 300 hp, so that that for a ton would not exceed 435 hp, probably not over 400 hp. This is just 1/400 part of the power claimed to be required by Mr. Swinburne.

The discrepancy between the power required for the apparatus of 500 cu. m and that of 100 cu. m capacity is easily accounted for by the greater efficiency to be expected from the larger apparatus.

It is well to remember that the first steam-propelled vessel which came from England to the shores of the United States carried copies of a pamphlet which proved mathematically the impossibility of a steamship ever crossing the Atlantic. Even in science the prediction of the impossible is dangerous.

Think what a fool anyone would have been thought 15 years ago who declared that a substance would eventually be found which gave out heat in large quantities without combustion and kept it up for an almost infinite time! Yet this impossibility of that recent date is now serving as the key to unlock many of Nature's doors hitherto sealed to us.

This letter is written in the hope that someone capable of doing so will explain these frightful instances of the "doctors disagreeing" for the benefit of an unfortunate engineer, himself unable to read the riddle.

John J. Smith.

[We trust that our correspondent's interesting letter will bring forward an instructive discussion and the desired information.

With respect to the theoretical point raised by him in the first place, we are unable to see how any discrepancy can be claimed between the classical theory of thermodynamics and Mr. Swinburne's statement that when two mutually inert gases mix (so that the mixture occupies a volume equal to the sum of the volumes of the two gases before the mixture) the entropy is increased. According to Clausius' principle that for any irreversible process in nature the entropy increases, Mr. Swinburne's statement means simply that the mixture of two gases in the way described is irreversible, i.e., that it is an impossibility to separate the two gases from the mixture again so as to bring them back into their original separate condition, without causing some other change as a matter of compensation. Mr. Swinburne's statement means that a separation of the gases, as just sketched, is impossible whatever kind of cyclically operating machine one may try for the purpose, the only condition being that when the gases are separated, everything else, including the condition of the cyclic machines, should be exactly in the same condition as at the beginning of the process. On closer analysis the impossibility of the imagined process will be found to lie in the fulfilment of the last-named condition.

To calculate numerically the increase of entropy involved in the mixture of the two gases we must devise an imaginary process by which (for instance, with the aid of imaginary semi-permeable diaphragms) the mixture of gases is separated into its constituents, every infinitesimal step of this process being a reversible equilibrium-step (i.i., if heat is given off to or absorbed from an outside heat reservoir there must be temperature equilibrium between our system of gases and the heat reservoir). The Clausius integral referred to by our correspondent, of the ratio of the infinitely small heat quantity to the absolute temperature, extended over our whole imaginary process, must then be calculated. In this way, which cannot now be sketched in greater detail, the numerical value of the increase of entropy due to the mixture of the two gases is found. The entropy increase, derived in a slightly different way, may be found, for instance, in Planck's Vorlesungen über Thermodynamik, §238, where it is shown to have an essentially positive value.

We may call attention here to an excellent and highly instructive little book by Mr. James Swinburne on "Entropy or Thermodynamics from an Engineer's Standpoint" (London, 1904). In this book some of the fundamental questions about entropy are clearly explained in accordance with classical thermodynamics; that is, in contradistinction to the vague statements often found in engineering textbooks—which would seem to be at the bottom of the theoretical scruples of our correspondent. As to the discrepancy between Mr. Swinburne's theoretical results and the practical results to which our correspondent refers, we trust an explanation will be forthcoming. —Editor.]

Heat Losses Through Furnace Walls.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Mr. Carl Hering, in your March number, page 125, makes some criticisms of remarks which I made in Chicago before the American Electrochemical Society in discussing Mr. Snyder's paper on the "Heat Losses Through Furnace Walls." My remarks are in Volume XVIII of the *Transactions* of this society, on pages 245 and 247. After carefully re-reading them and considering Mr. Hering's criticisms I feel convinced that the best answer to the latter is simply to repeat the former. My words were as follows:

"I think it is extremely important for electric furnace manufacturers, particularly, to study the question of the amount of heat transferred through the furnace walls. If they are experimenting with a given thickness of wall with a given furnace, there is one particular which it is important to bear in mind. Given an electric furnace with a wall of a given thickness, and experimenting with different materials in the walls to find the one which conducts the least heat from the furnace, you have a very good way of comparing the different materials by measuring the temperature of the outside of the furnace shell. The total heat loss from the furnace will vary with the temperature of its outside. I found a very convenient means of doing this by taking an iron-nickel thermo-couple and holding the junction against the furnace wall. In that way you can measure temperatures up to 500° C. With a given external surface the higher the temperature outside, the more heat you are losing; and the more efficient the heat insulation the lower the outside wall temperature will be." * * *

"I meant to say that for a given thickness of furnace wall, comparing different materials in that same thickness of furnace wall, you can measure the temperature of the outside and thus get a comparison of different materials composing a wall of given thickness."

And now, Mr. Editor, allow me to admit that I have repeated these words not for the pleasure there might be in refuting Mr. Hering's criticisms, but because of their real importance to all electric furnace constructors. If so keen a scientist as Mr. Hering is so slow in seeing their truth, and even rushes into print to confute them, it is surely worth while repeating them and commending them again to the serious attention of all interested, with the emphatic assurance that, as will be evident on proper reflection, they are important and true.

Lehigh University, March 12. Jos. W. Richards.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In the above letter of Professor Richards I notice that he does not quote all that he said in that original discussion, but that he has now omitted some of the very parts which gave rise to the present discussion; the portions now quoted in his letter, when read by themselves, would have called for a different comment than the one I made in my previous letter. I think that almost anyone reading all that he originally said, especially on page 246 of the *Transactions* (which page I notice he omits referring to in his letter), and realizing that the last paragraph quoted above beginning with

"I *meant* to say" certainly seems to signify that he did not mean what he had said before and was given as a *correction* of his former statements, will agree with me that, taken as a whole, it was quite confusing and that it was difficult to find out what he really did mean to say.

One of the confusing statements omitted from his present quotation is: "The higher the external temperature the less the heat gradient from the inside to the outside and, therefore, the less heat is being taken out of the furnace." But in the part quoted above he says that a higher outside temperature (hence a *less heat gradient*) means a *greater* loss, hence just the contrary; why should a less heat gradient sometimes mean a less loss and at other times a greater loss; he neither then nor now offers an explanation of this discrepancy or apparent contradiction. And in his apparent correction of this confusion (on page 247, namely, the last paragraph quoted by him above) he omits entirely to say whether he then meant that it is a higher or a lower outside temperature that indicates the greater loss. This certainly seems to indicate that he was not then sure which it was, and did not wish to commit himself.

It was because I thought others, like myself, might be confused by this apparent contradiction that I endeavored to show in the March issue that in the general case, barring the minor influences, the drop of temperature by itself, or the heat gradient, is not necessarily a measure of the relative losses, although it is in some specific cases.

Whatever Professor Richards meant to say, the main feature of his remarks certainly was that the temperature of the outside of the wall, and therefore the heat gradient when the thickness is the same, was a true measure of the loss, and was even "a *very good* way of comparing the different materials" in the walls. It is also a fact that in his final corrected statement he refrains from saying whether a greater heat gradient means a greater or a less loss.

I have endeavored to explain the true facts in the case in an article published elsewhere in this issue, the general conclusions in which are that the drop of temperature in the walls, as a general rule, is by no means a criterion of the loss, but that it is so in stated specific cases; that under certain specified conditions the higher the outside voltage (that is, the less the heat gradient) the less the loss, and under others, the greater the loss; but that in the latter case (which appears to be the one he now wants it understood that he meant) the outside temperature would be a very poor and in fact dangerously bad method of measuring the goodness of the material of the walls, and would therefore surely not be "a very good way of comparing different materials" and should be condemned rather than encouraged. It was therefore to his credit that in my first reply I did not assume that he wanted to be understood that he was referring to this particular case.

If, for instance, he were to measure the same furnace in summer and again in winter without knowing it was the same one he would have to erroneously conclude that the one measured in winter had the better wall material. Or if the supposedly constant inside temperatures in two different tests of two comparative furnaces happened to differ somewhat in the two cases, which is very likely to be the case, the relative positions of the two wall materials as to their insulating power might actually be reversed! I have shown by actual examples in that article that the outside temperatures, even under the conditions most favorable to Professor Richards' present apparent argument, which conditions it would be practically impossible to realize in practice, would vary so little with very widely differing materials that it would be very inadvisable to attempt to draw such conclusions from them as he recommends, or to place the reliance that he does on the results.

If Professor Richards now means what I understood the latter part of his original discussion to infer that he did not mean to say, namely, that the greater the heat gradient the less the loss, I can hardly assume all the blame for having at first misunderstood what he meant by the words he then used, and for being "so slow in seeing their truth" (sic), and I would respectfully suggest that he might have explained himself more clearly if he understood it clearly at that time.

My reply to his letter, therefore, is, that I regret that I cannot attach the same "real importance" which he does to either the "words" he used or to his method, and that I cannot endorse his "commending them (both) again to the serious attention of all interested, with the repeated assurance that, as will be evident on proper reflection, they are important." Whether my "reflections" on this subject are "proper" or improper must be judged from my views as expressed in the article on another page of this issue. If the statements in that article are true and correct, as I believe they are, and if they have assisted somewhat in clarifying the subject, I have no regret that I "even rushed into print," which under such circumstances I consider a professional duty to do.

Philadelphia, Pa., March 15. CARL HERING.

* * *

To the Editor of Metallurgical and Chemical Engineering:

SIR:—Referring to above communication from Mr. Hering I am sorry that he is apparently so slow in appreciating the correctness of my original remarks which he criticises.

My remarks were directed to bringing out two principles:

(1) If you keep all other conditions the same, and substitute one lining material for another in a furnace, then the better heat insulator said lining is the lower will be the temperature of the outside surface of the furnace and vice versa. Therefore, when experimenting with linings and substituting one material for another in the wall, the measurement of the outside surface temperature is a reliable index of the heat insulating quality of the wall material, the lower outside surface temperature indicating a better heat insulator and vice versa

(2) If you keep all other conditions the same, and substitute one kind of outside surface for another on a furnace, then the less heat radiating and conducting power said surface has the less heat will be lost from the furnace, although the outside surface temperature will be *higher* than it was before, and *per contra* the greater the heat radiating and conducting power said surface has the more heat will be lost from the furnace, although the outside surface temperature will be *lower* than it was before.

Fearing that the latter generalization was too difficult to be seen at once I expatiated upon it, explaining that the paradoxical statement would be better understood if it was realized that, in case (2), when varying the outside surface only, the higher the external surface temperature the less the heat gradient through the furnace wall, and therefore the less heat could pass from the furnace.

Mr. Hering has apparently not been able to see through these generalizations. He applies what I said about the heat gradient in the walls when varying the outside surface (case 2) to the conditions when varying the material in the walls and keeping the outside surface the same (case 1)—to which, of course, they do not apply.

In closing, I would say that I consider my original remarks, criticised by Mr. Hering, as clear and correct. They are not easy to understand, it is true, and if they had been merely self-evident platitudes there would have been no justification for my saying them. Mr. Hering has apparently, in good faith, been unable to understand them. If any reader of this journal is inclined to think the criticisms made upon them correct I would ask only one favor of him, viz., that he *study* carefully my original remarks, in Vol. XVIII of the *Transactions* of the American Electrochemical Society, pages 245, 246 and 247, and in doing so avoid the mistake which Mr. Hering made of confounding the two aspects of the experimentation there clearly distinguished from each other.

Lehigh University, March 16. JOSEPH W. RICHARDS.

The Opening of the Chemists' Building.

On a fine crisp spring day, full of glorious sunshine, in the presence of representatives of chemical science and industry, assembled from many parts of this country, the new Chemists' Building at 50-54 East Forty-first Street, New York City, was formally dedicated on the afternoon of March 17.

The building and equipment has been described in our issue of last December (vol. VIII, page 701). The purpose for which it was erected and the ideals which it represents are admirably stated in the opening address of Dr. Morris Loeb to whom more than any other individual the thanks of the profession are due for the transformation of the idealistic conception of a Chemists' Building into an actual and beautiful reality.

Dedication Exercises

Dr. Morris Loeb, as president of the Chemists' Building Company, made the following address:

"I rise to welcome you on behalf of the directors and stock-

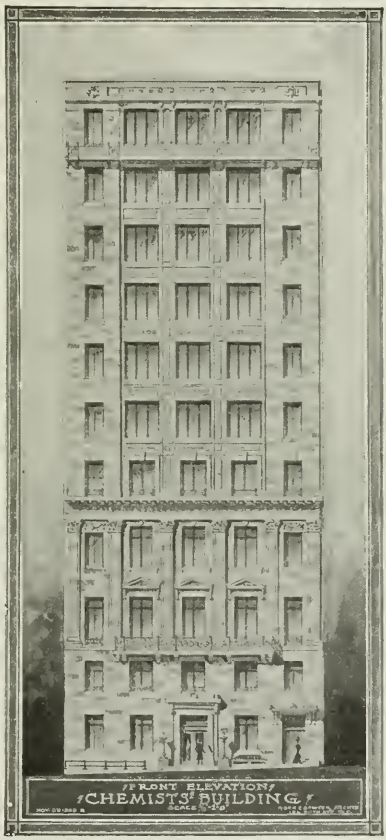
MORRIS LOEB

holders of the Chemists' Building Company and to thank you for the interest which your presence indicates in the formal opening of a building which we believe to be the first of its kind, not only in this country, but on earth. It is true that Berlin possesses in the Hofmann-Haus a home for the German Chemical Society and that London owes to the munificence of the late Ludwig Mond its Faraday Laboratories for Chemical and Physical Research. But this new building in which you find yourselves is planned to serve under one roof the social, intellectual, and practical needs of the chemical profession not of New York alone, but of our whole beloved country.

"The means for its construction have been furnished by men, many of whom can expect to share to but a slight degree in the benefits of the Chemists' Club, which occupies so much of its floor space. These shareholders see in it the incarnation of some of the ideals that led them to the pursuit of chemistry, pure or applied, as their lifework.

"For, strange as it may seem to the layman, who has seen the ugliest blots on a landscape designated as chemical factories, who has sniffed with disgust a chemical odor, has been urged to believe that the chemist's shadow contaminates pure foods, and has been taught in school that alchemy spelled fraud and sorcery, our science is one calculated to develop the ideal side of human nature, and the chemist, more perhaps than the votary of natural science or the devotee of the so-called humanities, is led to an intense interest in human development.

"Our science aspires not only to know, but also to do. On the one hand, it leads us to delve into the secrets of nature, in the minute atom as well as in the far distant stars, in the living cell as well as in the crystallized relics of the convulsions from which this earth was born; on the other, it leads us to apply this knowledge to the immediate needs of man, be it in safeguarding his health, in ministering to his material or esthteic



CHEMISTS' BUILDING

wants or in regulating his commerce and in facilitating his utilization of the earth's resources. These many points of contact with nature and with human interest will be the theme of the eminent men whom I shall have the privilege of introducing this afternoon and will be illustrated at greater length in the scientific meetings which are to follow; it is enough that we recognize at this moment that this versatility of method and of purpose must necessarily enlarge the viewpoint of the chemist, and to seek therein the motives for the ready cooperation in the present enterprise.

"Our shareholders content themselves with a moderate return for their money and have agreed that surplus profits shall accure to the benefit of chemical science. They hope that the facilities afforded within these walls will redound to the benefit of mankind and the prosperity of the country.

"May I emphasize the word 'facilities'? There are two ways

of aiding a man or a cause: by addition to the income or reduction of the expense. The pecuniary result to the beneficiary may be the same, but the moral one is far different; it is not only the beggar who is pauperized by the cash gift and uplifted by the aid which enables him to earn his own livelihood. Arts and sciences may be stimulated by prizes and scholarships beyond a doubt, but the relation between donor and recipient is not free from restraint, and the probability of human error in the selection of the right incumbent makes the method a wasteful one at best.

"Far better is it to remove those obstacles which hamper all work equally and are felt more severely by those whose means are restricted and who have not yet earned the recognition of the world at large. The laboratory student is encumbered by certain restrictions in America more than elsewhere. The higher price of commodities affects him in many ways besides the higher cost of living, rent of laboratory, installation of equipment, purchase of supplies, salary of assistant, acquisition of books. The advanced cost of labor militates against the construction of certain grades of apparatus and the preparation of the rarer chemicals in this country; and a curiously unscientific tariff law, while pretending to lift the duty from articles required for educational purposes, practically forces the colleges to make their purchases abroad and prevents American dealers from carrying an adequate selection of imported material. It is no exaggeration to state that this duty-free importation clause, as interpreted by the United States Treasury Department, forces the American chemist to wait from two to three months before making an experiment for which he could obtain his material in two or three days if he were working abroad.

"To remove these disadvantages in time and cost, to provide easy access to books and apparatus, to make room for the independent scientific worker are the ideals which hovered before the eyes of those who planned this present enterprise. Time will show whether they can all be realized, but whatever is done in this beautiful building, which we are about to dedicate, must open free opportunities to all and show favoritism toward none if the trust imposed upon its management be administered in the spirit of those who have contributed toward its erection.

"A library of the highest scientific importance and a museum of chemical substances will be available for every reputable chemist; laboratories for temporary as well as permanent use will be at the disposal of the earnest student; help and advice will be extended to the struggling beginner; good comradeship and hearty co-operation will characterize the Chemists' Club, and this auditorium, soon to be named after the first great chemist of American birth, will ever minister to his ideal of the application of science to the useful arts."

Dr. Loeb concluded with words of appreciation for the work of Messrs. York & Sawyer, the architects, of Mr. Ralph C. Crow and his associates in the construction company, of Messrs. Marks & Woodwell, the consulting engineers and of Mr. Chas. Eidlitz and Messrs. Black & Boyd, the contractors for the electrical and lighting equipment. "And now, ladies and gentlemen, I have given you an account of the empty shell. The spirit which is to animate it will be brought to your minds by the speakers whom I have the privilege to introduce—master minds of our science and guides of the future of its leading organizations."

Dr. Loeb was followed by Dr. Edward S. Morley, who spoke as the honorary president of the Eighth International Congress of Applied Chemistry, to be held in September, 1912, in this country. While the organization of the congress so far consists of officers only and no crew, yet the congress rejoices in the opening of the Chemists' Building, which will be its headquarters, and the congress transmits its hearty congratulations.

Prof. Alexander Smith spoke as president of the American Chemical Society on research work. Two requirements are absolutely necessary in an investigator—first, a proper training, and, second, a true spirit of research or thirst of discovery. Both belong together. Professor Smith explained how the Chemical Society had helped possible investigators to find themselves and expressed the conviction that the new Chemists' Club Building would offer magnificent opportunities in the same direction.

A letter from Prof. Ira Remsen, president of Johns Hopkins University, was read, expressing his regrets of being forced to be absent. As past president of the Society of Chemical Industry Prof. Remsen referred to the relations between science and industry.

A letter from Prof. Edgar F. Smith, provost of the University of Pennsylvania, also expressed the writer's sincere regrets of not being able to be present.

Prof. William H. Walker, of the Massachusetts Institute, then spoke as president of the American Electrochemical Society. The field of chemical science is now so large that no one person can expect to cultivate more than a small portion of it. Electrochemistry deals with the chemical changes brought about through the application of electrical energy, and within this limitation has grown up a strong, virile organization, international in its scope, the American Electrochemical Society.

But, as Dr. Walker pointed out, "the specialization of to-day tends to carry us apart—tends to a divergence of interest. This new chemists' building will function as a center to which every chemist, however diverse his interest, will be drawn. There was a time when the advice to a young man was 'Paddle your own canoe.' Each chemist did this to so great an extent that he worked for himself, by himself, without thought of others. The national chemical societies have already done a grand, good work in bringing men engaged in chemistry together, but this Chemists' Building will be an additional and most potent factor in placing the profession of chemistry where it by right of its importance belongs. No longer will the cry be 'Paddle your own canoe,' but, rather, 'Get the stroke and pull together.' It is this sentiment which is exemplified in the Chemists' Building. Here we can present a united front, and strive for the further uplift of the chemical profession and the community."

To Dr. Loeb and the men who have stood by him Professor Walker tendered the grateful thanks of the American Electrochemical Society. "And again I would greet the Chemists' Club, and wish for it many long years of usefulness in which to enjoy the splendid new building which to-day is theirs."

Prof. Wilder D. Bancroft, of Cornell University, then presented in his characteristic humorous manner a brief yet suggestive address on chemical education. He said that the trend of the many discussions in recent years had been how to teach a man so that he becomes a technical chemist, so that he knows all about machinery, about the handling of materials on a large and small scale, about the handling of men, about questions of costs, etc.

All these, Professor Bancroft said, are valuable and interesting problems. But people who want to instruct students in these subjects overlook several very important points. Firstly, that it would require a prohibitive expenditure of time. Secondly, by giving a man a proper drill, can you really make him a works manager? Why is a works manager paid a big salary? Because he is relied upon to pull the plant out of unforeseen difficulties. An ideal plant, running with mathematical accuracy, would not need a manager.

Professor Bancroft thinks there is something wrong with our methods of education, but he finds the trouble to be rather in another direction. Every young boy asks in a few minutes a great many more times "why"? than his parents can ever answer. But when the same boy has passed ten years through a school and four years through a university he no longer asks "why"? Why this is so—this would be a good subject of future discussions tending toward an improvement in chemical education.

Then followed the unveiling of the tablet of Count Rumford, after whom, as the first great American chemist, the Auditorium is named. Dr. Frank W. Clarke, of the United States Geological Survey, gave a very witty history of Count Rumford's life. He spoke of Rumford as one of the real great Americans and dwelt on his statesmanship. He emphasized that Rumford, an American, founded the Royal Institution in London. Yet his greatest discovery was Humphry Davy, and the latter discovered Faraday.

Dr. Loeb then explained the building, its design and equipment, and handed the keys of the clubrooms of the Chemists' Club over to its president, Dr. Russell W. Moore, who replied in a felicitous little speech.

This concluded the formal dedication exercises, which were followed by a reception in the clubrooms.

Scientific Sessions and Banquet.

The evening of Friday, March 17, and the morning and afternoon of Saturday, March 18, were devoted to scientific sessions held under the auspices of the New York sections of the national chemical societies.

The meeting of the New York section of the *American Chemical Society* began with an elaborate historical and philosophical address by the chairman, Prof. Charles Baskerville, of the College of the City of New York.

Prof. Jacques Loeb, of the Rockefeller Institute for Medical Research, followed with a suggestive lecture on the characteristics of living matter from the physico-chemical point of view.

Prof. R. B. Moore, of Butler College, Indianapolis, gave a lecture on the rare gases of the atmosphere. The lecture was illustrated by a series of highly interesting experiments, in which the lecturer isolated with great skill and success the rare gases from atmospheric air.

While the session of the American Chemical Society was thus pitched in a highly scientific key, the proceedings of the other two societies on the next day broadened in their effects, bringing out the human not less than the technical and scientific sides of engineering.

The session of the New York section of the *American Electrochemical Society* started with an address of the chairman, Mr. Elmer A. Sperry, who emphasized that of all branches of applied chemistry electrochemistry is most specifically American.

Dr. W. R. Whitney, chief of the Research Laboratory of the General Electric Company, followed with a lecture on "mental catalysis." This admirable and inspiring address on idealism in science and engineering is printed in full at the conclusion of this report.

Prof. Wilder D. Bancroft then lectured in a very interesting manner on the chemistry of phosphorescence, showing how it is possible to distinguish the chemical reactions which play a part in phosphorescence. After the subject of phosphorescence has been studied in great detail from a purely physical point of view, Dr. Bancroft's way of looking at it from the chemist's standpoint is decidedly novel and promises important results.

The session of the New York section of the *Society of Chemical Industry* in the afternoon began with an interesting address by the chairman, Dr. Charles F. McKenna, who in conclusion read a letter from Hon. James Bryce expressing his regrets of not being able to be with the society on this occasion.

Prof. Wm. P. Mason, of the Rensselaer Polytechnic Institute, followed with a very instructive address on the contributions of chemistry to sanitation, especially water purification.

The session was concluded by an address of the doyen of the chemical professions in the United States, Prof. Chas. F. Chandler, who gave interesting personal reminiscences of the history of chemistry in New York City.

As in classic Greece a serious dramatic trilogy was always followed by a satyrplay, thus the trilogy of serious scientific sessions was followed on Saturday night by the first banquet of the Chemists' Club in the new building.

It was a decided success, in spite of the fact that it was almost too well attended. Frolicsome merriment reigned supreme, and the toastmaster, President Russell W. Moore, and the master of the revels, Mr. Elwood Hendrick, must be highly complimented on their success. Dr. Moore's chief speech was in the presentation of a large silver loving cup to Dr. Loeb—as Dr. Chandler said, only a token of our affection, not a measure. Mr. Hendrick contributed delightful newspaper stories and remarkable telegrams and letters.

Other speakers were Dr. Loeb, Dr. Schweitzer, Dr. McKenna, Mr. Plaut, Prof. Alexander Smith, Dr. Rosengarten, Mr. Parker, Dr. Chandler and Mr. Jacob Hasslacher, whose concluding words were that while the English language had no exact equivalent for the German Gemütlichkeit, the Chemists' Club was the nearest he could think of.

The celebration was fittingly concluded by a concert of the Olive Mead Quartet, on Sunday afternoon, with a program of Mozart, Tschaikowsky, Mendelssohn, and Grieg.

* * *

Mental Catalysis.*

By Dr. W. R. Whitney.

Perhaps you have asked yourself the question, what has this subject of mental catalysis to do with electrochemistry? Therefore, I want to explain.

One might justly expect from me at this time a paper embodying the results of some specific electrochemical research, but when I was asked by your committee to prepare a paper my first impulse was to go back to first principles, and as the title had to be given before the paper was started, I chose a title which might cover a line of thought along which I had already quietly enjoyed some study. You know that in most extended chemical researches a great deal depends on a study of what in Germany we called our "Ausgangsmaterial." A long line of interconnected reactions, of properties and of products are evolved from a certain "Ausgangsmaterial," and we are probably all familiar with the way in which this whole line may be altered by only a small change in the purity of our "Ausgangsmaterial." So, for our science in general, I am going back a few minutes to consider our Ausgangsmaterial.

I suppose that every chemist who is deeply interested in his work finds himself sometimes wondering: Am I doing this in the biggest way, or am I a small machine, working only with my hands? Perhaps I am only a little more complex machine, using a stock of knowledge and certain trained habits merely as a means of livelihood, just as some engine uses steam and eccentrics. Or, finally, is it possible to be what is called a free moral agent, using knowledge, training, talents, and all to their ideal efficiency?

Those of you who have read Maeterlinck's "Life of the Bee" know that it seems as though the bee-hive represented the acme of communistic perfection. Yet we are apparently more highly endowed than bees, and much more is expected of us There seems to be something in us which calls for a continually widening horizon. We must do more than work.

This is an attempt to consider for a moment some of the laws of forces which may underlie successful work and advances in its broad, its only satisfying sense. Of course there are such forces and such laws. We all feel the force of a great, far-seeing mind. We can easily point to our leaders of the past. Our history itself is largely the product of time into some mental forces. I want to imagine that the force which determines advance in any line is *idealism*, and I call it the catalyser. I want to point out that this force in its growth is subject to two entirely different influences, which may be looked into and studied separately. These I may call the *conceptive* and *receptive*. In each of these we all take part. A

*An address made at the extraordinary meeting of the American Electrochemical Society, held at the opening exercises of the new Chemists' Building in New York City on March 18, 1911.

club like this is a place where both the conceptive and receptive influences should be very prevalent.

A number of years ago I overheard a statement which was not intended as complimentary, in which a young chemist was referred to as an idealist. I think the intention of the speaker was to use the word as an antonym of the word "practical." This has often been recalled to my mind, and the results of some thinking on the subject form the matter of this brief talk on Metal Catalysis.

There is no profession where idealism can play a more important part than in our own. Why? Well, because we possess all the elements for material realizations. The exact bearing of idealism is fairly clear to me, and I want to make it clear to you.

A methodical chemist who is solely trained to observe and to record may *enormously contribute* to the science without *advancing* it appreciably. By advance, I mean to infer an increase in our breadth of horizon. I may be faithful, industrious and well educated, and contribute largely to the work of my subject, but there is something which will tell more certainly upon my relation to my work than my erudition. I think this criterion is idealism.

Far be it from me to compare the work of one kind of chemist with that of another, for until we shall have learned just exactly *why* and how we are, we are not in a logical position to compare one another's contributions. I rather want to interest you for a few minutes in the peculiar *attractiveness* of idealism.

"But is this a real thing? Is it practical"? I hear you ask. I answer, "It is as real as we are." Consider its growth. It is safe to assume that our earliest ancestors were gifted with as much as or more physical strength than we are. As organic entities, apparently tending to increase the entropy of the universe, they did not differ much from ourselves. In the stone age a dietetic study would have shown nearly the present calorific change and metabolism. I do not mean to raise the question whether we are better than they or not, though that should be permitted to an idealist. But I expect you to admit that we are different and are growing more so every day.

Our horizon is broader. Now I want to point out that it is our idealism that accounts for the difference. I call idealism that developed power of *prevision* of the more perfect, that mental elasticity which sees improved things before they arrive, which may even see some that never arrive, and which power has hope and optimism for pressure indicators. This is the catalyser.

The doctors of medicine and the specialists in diseases have shown us how, under certain conditions, contagions appear and spread; how they are carried from one plant or animal to another, under what conditions they thrive and how specific immunity may be procured. Such discoveries (relating to the realities of life) apply directly to the ideals. It can be seen in the histories of our mental growth. For example, the spores of plastic art were evinced in the stone age, but the idealism did not develop very rapidly until much later. But we find it almost as widespread and advanced in Egyptian and Greek sculpture before the time of Christ as it is to-day. There was a period and a place in which it made most rapid strides.

Idealism, as expressed in marble, which first had mental form in the minds of a few idealists, spread by their contact with others and soon reached a splendid state of advancement. Many centuries later idealists from Giotto, de Vinci, Michael Angelo and the painters of the fifteenth century spread the idealism of painting so that in their eras the world very rapidly made its greatest advances in painting and in architectural art.

We are so accustomed to the laws governing idealism that we often fail to realize them. A few idealists partly realized their visions in some such ways, and world-advances were made. That is, permanent additions were made to the diameter of the world's mental horizon. Through all these epochs the realist lived. The cost of food, expressed in labor, remained about the same. The question whether a purely mental enjoyment was a utility had long been put, and answered as now. Among the things which kept on acting was idealism.

In the chemist's field we see the value of idealism in matters both small and large. Usually the first expression of an ideal is so unrealistic as to meet opposition or at least friction. I think we can consider some of our hypotheses as ideals. Consider for a moment the benzene ring. We all know its value to us as an idea, but it was once an ideal. The even more idealistic theories of disease immunity, such as that proposed by Paul Ehrlich, with its fantastic receptors and side chains, while leading to very important practical results, still appeal to many as too speculative, too idealistic. But they are more than valuable. They hasten our advance, they catalyse.

I do not care to raise the question of the exact accuracy of the conceptions of the idealist. This we need never know. But as trees are known by their fruits, we should measure the value to us of idealism by the products. We may admit that what idealism accomplishes for us might be reached in time without it. This is the earmark of a catalyser. In catalysis the velocity of a reaction is increased by agents which still exist, unaltered, after the reaction. In many cases the catalysis is plainly one of contact. I have known several men who worked in Edison's laboratory. They are still a definite type of idealist.

I also recall how, just nine years ago, a small group of 11 men actuated by an ideal in the mind of two or three started in Philadelphia the American Electrochemical Society. My reason for referring to it is to point out that it was a *lonesome mental conception* before it became a group of men. I am trying to point out the value of such ideas and their fertilization. I want you to realize their frequent frailty, their need of nurture and their final possible power.

I find an application in this occasion to-day. An epoch-making event is just transpiring. In nearly the largest city in the world the first clubhouse and guild hall devoted to our science is being inaugurated. It was first an ideal, a vision in the mind of a single man. He could have slighted it. He could have said to himself: "We have always gotten along without this thing. Why disturb the equilibrium of the day?" But he persisted, and started a thread of history which will never break. The ideal preceded the real, the mental vision preceded the physical vision. That is the law. The ideal catalised the reaction and we have the product. This clubhouse will do much for idealism, and all I can do now is to point out ways along which it will be done.

The deep student of chemistry, confined entirely to his books and laboratory, has ideals, but contact with others of his calling will contribute enormously to his information and incentives and must, therefore, direct and influence his ideals. This is so well known as to need no enlargement.

The teacher to whom we owe so much and on whom such a great responsibility rests can be aided, through this organization, with increased efficiency. Here he will come into contact with others of his profession and can gain from them encouragement for his ideals. He will also learn of the ideals and advances of the industries and increase his power of imparting ideals to his students.

As I still count myself among the teachers of chemistry and am so counted in Institute catalogs I may be permitted to say that in the teaching of science there is still very much room for improvement. I would go further and say that we have scarcely learned how to teach idealism *at all* and that we are continually in danger of destroying what idealism comes under our observation by the very methods of this system we employ. Most teachers have probably had occasion to notice the loss of what he calls enthusiasm in some student as the latter has been taught more. Of course, his enthusiasm and optimism ought always to grow greater with added powers instead of becoming less.

One thing needed by us as Americans is more idealism. In our times, I think I am safe in saying, idealism is not greatly influenced by climatic conditions, but it certainly is by environment. I don't thnk there is proportionally as much idealism in the English as in the French or German of to-day. I know more about us Americans. We are generally defective in this respect. We are aggressive. We are realists and often, basing our energies upon foreign visions, we can do the rest. This is most marked in the industries, and we know it well in physics and chemistry; but in art and literature we are still copyists. In medicine and surgery we show to better advantage, though I think most of the pioneer conceptions are still of foreign make.

In other words, I believe we have, as Americans, plenty of latent energy, but are still deficient in idealism. We can and do master the problems with which we come into contact, but largely for themselves and possibly for the pleasure of doing something useful. This alone may be commendable, but it can be improved.

A would-be idealist cannot be expected to produce useful ideals if he is out of contact with his fellow-man. We need the idealist as a guide, but a guide who is so far ahead as to be out of sight is a poor guide. This means that the contact catalyser must really be in contact to catalyse.

Huxley, in an address as the rector at Aberdeen, says: "The man who is all morality and intellect, although he may be good and even great, is, after all, only half a man. There is beauty in the moral world and in the intellectual world, but there is also beauty which is neither moral nor intellectual—the beauty of the world of art. There are men who are devoid of the power of seeing it, as there are men born deaf and blind, and the loss of those, as of these, is simply infinite. There are others in whom it is an overpowering passion, happy men born with the productive (or at the lowest) the appreciative genius of the artist. But in the mass of mankind the aesthetic faculty, like the reasoning power and the moral sense, needs to be roused, directed and cultivated."

I consider idealism a name for this faculty to which he refers. It is the faculty of seeing beyond and over the physical dimensions of things. It is the power of being the parent of plans. It is that something which makes us call certain men artists in their profession.

The start we all get in the physical sciences by being taught in laboratories especially equipped to insure contact of student with the thing, rather than with the book or with the man, is an idealism realized in our own day. It was only a vision seen by a few physicists less than a hundred years ago, and this led to chemical and physical laboratories equipped to give experimental work to students. I only mention this to show how we are realizing the benefits of a condition which a short time ago was only an idealistic dream.

I am quite sure that within the lifetime of some of us here he would have been smilingly and pityingly called an idealist who had dared predict an 11-story building for a chemists' *club*. It seems realistic enough to us now, but half a century ago there were hardly chemists enough in the country to keep a chemical society alive, and they fined themselves for absences from meetings, too. Such advances are not exactly like "Topsy" in "Uncle Tom's Cabin." They don't just grow. They can be traced to some ideal in every case.

In a hearing before the Massachusetts Legislature the other day, Mr. F. P. Fish, formerly president of the Bell Telephone Company, made the following remarks, which are idealistic, but warranted, and are of interest to us:

"I should like to prophesy that we are really just at the beginning of this industrial development. During the last generation we have seen the extraordinary development of electricity, which is not by any manner of means completed. I am satisfied that during the next generation—the next two generations—there is going to be a development in chemistry which will far surpass in its importance and value to the human race that of electricity in the last few years. A development in chemistry which is going to revolutionize methods of manufacture, and, more than that, going to revolutionize methods of agriculture. I personally believe that in a generation or two we shall see the deserted farms of New England, if there are any, blooming with vegetation because of the work that is done by chemists. * * *"

Idealism? Certainly, but practical to the core. Why? Because it helps produce. It catalyses. This spirit is almost invaluable in assisting in realization. Bare mechanical work in any field is a heartless thing. Its tendency is to habit and unaltering self-perpetuation, but the idealist interferes and keeps pointing to something more perfect, more interesting.

Henry Van Dyke, in writing on creative education, said:

"The right ideal of education in a democracy is the creative ideal. It does not seek to adorn men with certain rare accomplishments which shall be the marks of a Braminical caste. It does not seek to train men for certain practical pursuits with an eye single to their own advantage. It seeks, by a vital culture, to create new men and new kinds of men who shall be of ever-increasing worth to the republic and to mankind." And, again: "It has four definite marks: the power to see clearly, the power to imagine vividly, the power to think independently and the power to will nobly. These are the objects that the creative ideal sets before us."

Herbert Spencer also saw the operation of idealism when he said that society was a growth and not a manufacture and has its laws of evolution. He says: "Our immense manufacturing system, with its multitudinous inventions supplying both home and foreign consumers, * * * have been naturally and not artificially originated. * * * Knowledge developing into science (which has become so vast in mass that no one can grasp a tithe of it and which now guides productive activities at large) has resulted from the working of individuals prompted not by the ruling agency, but by their own inclinations." It is the direction given to these inclinations that determines idealism. This is a flexible factor. It depends upon us in both the efferent and afferent, our production of ideals and our reception of them.

One can hardly look into the history of any leader of a profession without seeing the effect of idealism, and yet we are more apt to think first of the individual's accumulated knowledge or his products. Think, for a moment, of the idealism of a Faraday. It is really more to be admired than his tangible work. It continues to operate long after he has passed away. The way he undertook his work we call ideal. Everyone admires his approach to his subject, his deference. The ions he idealized we know by name and by weight. The lines of the magnetic field, which were an ideal to him, have the bearing of working realities to us to-day.

I did not start with the thought that I would be able to perfectly declare the genesis of idealism, or mental catalysis, any more than I might explain chemical catalysis. But just as we know a few of the laws governing the latter, so we may cite a few principles of the former. Idealism grows better in a warm, receptive atmosphere than in a chilly or doubtful one. In other words, while I do not claim at this point that idealism can be made autogenetic or that one can will himself an idealist, I know that one may increase the fertility of the soil in which the plant grows.

I cannot help thinking at this moment of the late S. P. Langley, of the Smithsonian Institute. As an American citizen I am ashamed of myself at the mention of his name. He was called an idealist. One of his ideals had to do with aeronautics. I believe he did more to advance the knowledge of the subject than anyone prior to his day. He did not capitalize his idealism, either. He built a machine which was almost identical with our present successful types, and it flew half a mile under its own power. It was as healthy a set of experiments as we American people have ever paid for, but because his ideals were not completely realized in the first test we laughed

him to death. We may know enough as a practical people, our morals may accord with any standard erected, but our appreciation of idealism needs a lot of fertilizer.

It is in such a place as this club that idealism in chemistry will be fostered. The atmosphere can be made to favor its growth. Instead of shunning some idealist as a crank (and the pet of his idealism as a freak) we can show him we have learned that most essentially new things have been called freaks ever since the word was known. What is better, perhaps, we can learn that it greatly helps in the realization of ideals to assist them.

We recognize the effect of idealism when we see it in such art as that of Michael Angelo. We see, too, that there must have been a great deal of idealism back of the wingless Victory of the Acropolis or the winged Victory of Samothrace, because even now they are perfect to us, but we ought also to find it nearer home. We say it is in poetry, but it may also lie in prose. If it belongs to art, it also belongs to science. If it has existed, it still exists. Perhaps the law of conservation may be applied to it, as it is to mass and energy.

It certainly does not grow as a result of mere work, however hard. It is not measured in watt-hours or foot-pounds. It cannot be forced. Dr. Gulick has said: "Compulsion fails to account for the greatest things in the world. One cannot imagine, for example, that those poems which bless us with their beauty and strength, with their vision and inspiration, were written under a compelling sense of duty. Such poems as Mrs. Browning's "Portuguese Sonnets" spring from sources other than those of necessity. It is so with the world's great statues. There was a vision of beauty, an ideal within the souls of the men who made them, and this ideal was so compelling that they worked it out, oftentimes at great personal sacrifice." He also says, "When we say to a man, 'Play the game,' we mean treat the situation as an ideal." It means to drop all selfish individual considerations and to meet the real situation by ideal means.

There are times when the most of us feel that we know more about mental paralysis than about mental catalysis. At the end of a day's work, when the practical difficulties seem to have been particularly devised and peculiarly adapted to meet our special insufficiencies, we are apt to feel ourselves far removed from the ideal of anything. A clubhouse such as this ought to help dispel such feelings. When we are unable to bring forth pet flowers of idealism for the sake of the fertilization that others can give them, we can at least carry a little watering-pot for the opening bud of some other fellow, and that's a use for a club.

Research Laboratory,
General Electric Company.

The Arizona Copper Company has issued its annual report for the year ending Sept. 30, 1910. During the year 599,250 dry tons of sulphide ore were concentrated, the ratio of concentration being 5.14 to 1. Improvements are under way which will result in combining the No. 5 concentrator into the No. 6, greatly enlarging the capacity of the latter and permitting the treatment of a lower grade of ore than formerly. It is expected that the changes will be completed by the middle of this year. The oxide concentrator treated 115,223 dry tons of ore and leached 102,381 dry tons of tailings. The copper recovered amounted to 11.3 per cent of the total copper produced during the year. The sulphuric acid plant produced 2971.5 tons of acid. In the smelting department an average of 3.8 furnaces were in blast, smelting ore and concentrate amounting to 158,532 tons. The average yield of copper from this material was 10.14 per cent. The company has been carrying on extensive experiments in metallurgical treatment, which will be of benefit in future changes or improvements in the plant. The output of copper for February, 1911, was 1430 tons.

The Evolution of Portland Cement Processes.*

By Charles F. McKenna, Ph.D.

In the Portland cement industry there is a perpetual but healthy unrest. No sooner is one feature of marked improvement successfully brought forward producing a suggestion of finality than several minor progessive steps are seen to tend together toward such economic advantages as to constitute practically again a new process. On reviewing the subject I have felt that the history has the elements of a romance, if it were not for the overpowering newness of it all, and I have felt that the near future still has surprises in store.

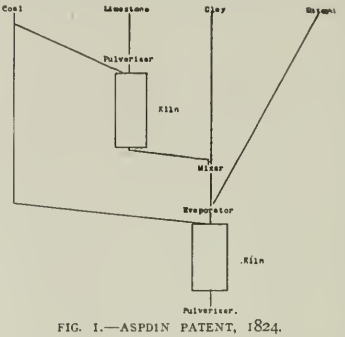


FIG. 1.—ASPDIN PATENT, 1824.

I hope I may leave this impression upon you, and also in rehearsing it to show properly that while praise is due to the mechanical engineer, it must also be given to the chemist. Indeed, it is generally felt to-day that it is to chemical engineering that the industry must appeal most strongly in the future, and that progress and economy is promised more surely because the leaders have realized that the trained and experienced chemical engineer is best fitted to cope with the new problems and avoid some errors similar to those of the past.

We have seen a product obtained in a most primitive fashion only 50 years ago now produced throughout the world in millions of tons annually, and with such economy that for 1 cent 12 lb. of raw material will be taken from the earth, dried, ground, calcined and vitrified, and the product ground again. It would seem as if the use of fuel, machinery, human hands and human brains could not go further. Yet there is ample scope for improvement and economies as you will easily perceive.

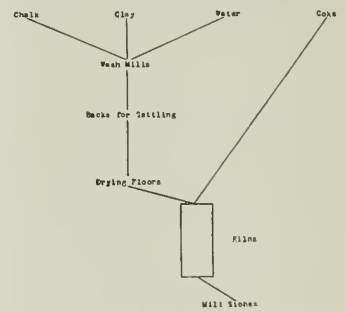

FIG. 2.—OLD ENGLISH PROCESS.

Aspdin's invention seemed a simple one (Fig. 1). He pulverized limestone, burned it, mixed clay with it and water to a plastic mass, after which this was dried and burned in a kiln and the product pulverized.

Much experimenting had previously been done by himself and by many engineers throughout the world to try to discover the cause for hydraulicity, but beyond perceiving the value of the argillaceous elements in the limestone, none of them discerned the important part played by high temperatures in the burning. Aspdin was the first to combine these elements properly, and burn much of it properly.

It is very probable that he did not know that the vitrified pieces of his clinker made the only true Portland cement, and it is also very probable that other experimenters had obtained vitrified Portland clinker when burning natural argillaceous

*Presidential address delivered before the American Institute of Chemical Engineers in December, 1910.

limestone and did not recognize its special value at the time.

The success of Aspdin's work was noted in other countrys. but for the first 25 years its greatest vogue was in England. Many modifications had in the mean time been introduced there and the typical English process of the day was one (Fig. 2) in which chalk and clay were introduced with an excess of water into wash mills—large circular basins with revolving harrows—and after incorporating here, transferred to large backs or settling reservoirs from which the surplus water was drawn off. It took about six weeks to settle.

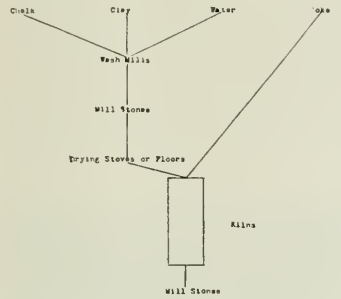

FIG. 3.—LATER ENGLISH AND CONTINENTAL PROCESS, SEMI-WET, AFTER 1870.

The stiff mud from these was dried on floors heated from below and then charged into the kilns in which coke or coke dust was the fuel. The product was ground by burr stones.

The juxtaposition of chalk deposits near the Thames and the Medway and the mud banks of these rivers, together with a plentiful supply of coke from the gas works of London caused a large development of this industry near the world's greatest city.

About the middle of the last century the industry was fairly started in Germany, and was destined there to take a development characteristic of that country, and in it the skill of the chemist was successfully given free scope.

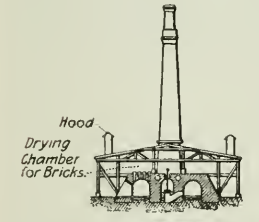

FIG. 4.—HOFFMAN CONTINUOUS KILN.

The favorite method ultimately developing in Europe (Fig. 3), sometimes called the semi-wet process, was one in which less water was used in the beginning, and in which air incorporating mill was used on the stiff mixture. This saved the time previously allowed for the very wet mixture to settle in the backs.

When you add good chemical control of the original proportions and this feature of incorporation by grinding you see how progress was being made. This is what the Germans particularly did.

The kilns first used were the ordinary lime kilns, later increased in height for the purpose of increasing the heat.

Later in some of the greatest of the German works the Hoffman continuous kiln (Fig. 4) was much used in which compartments are charged and discharged and the flat roof used for drying.

In Germany the Dietzsch became the favorite in later years. In this kiln (Fig. 5) the material is preheated in the upper part as usual, and in the central part into which it is drawn by the workmen operating through the fire door it is particularly exposed to high heat by reason of the construction of the furnace here. The clinker gradually cools as it sinks below.

The Schöfer or Aalborg kiln is an upright one like the Dietzsch and has a zone of high heat.

Now investigators in this country in the decade after the close of the Civil War noting that the Portland cement imported from Germany and England was selling for $5 a barrel sought eagerly for materials from which to make it.

It was thought that a soft chalk must be found before any economical works could be thought of. This was the view of all English cement makers who were visiting this country at one time with a view of starting business.

But David F. Saylor, who was making natural cement from one kind of rock at Siegfried's Bridge, near Allentown, Pa., began experimenting in the early seventies upon a mixture of this rock with a purer limestone. He produced in effect a true Portland cement (Fig. 6) and he was destined to be the first in

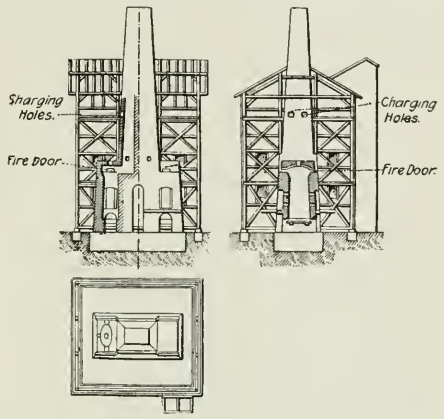

FIG. 5.—DIETZSCH KILN

a long line of American inventors, each of whom can be said to have modified the industry so fundamentally and markedly as to the world in each step forward.

The first kiln used to produce Portland cement in America was a bottle kiln of the type used in England. Subsequently at Coplay, Pa., the seat of the industry, the Schofer kiln was built.

Saylor's American Portland was the recognized and only important American Portland cement for a few years after this till Antonio Navarro, a capitalist, entered the business. Ransome had patented a rotary kiln in England in the seventies, but it was not practically adopted there. In the early eighties Navarro secured the American rights, and what is now the present Atlas Portland Cement Company was started at Northampton, Pa. Whittaker also used a similar kiln, and both of these used oil as a fuel.

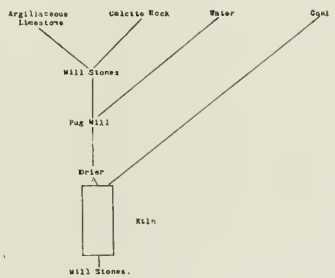

FIG. 6.—FIRST AMERICAN PROCESS. (SAYLOR. ABOUT 1875.)

This was entirely a dry process (Fig. 7). It is sometimes thought that in no country but America was it the practice in those days to eliminate the wash mill and to incoroporate dry. This is not so; for in Europe from 1885 to 1895 there were several plants operating on the process of: First, crushing and pulverizing dry; second, mixing and moistening with about 15 per cent. water; third, moulding into bricks; fourth, burning; fifth, grinding clinker.

In 1895 Hurry and Seaman were amongst the first to operate

in this country by a process which was destined to be of great influence the world over in the industry. This was the process for using as the fuel powdered coal blown into the kilns. The product was so well burned and so much in volume was continuously produced that the method rapidly extended. The clinker thus produced made a cement which was very quick setting. If a change of the composition of the raw materials was made to avoid this the cement was unsound, particularly upon trial by the quick method of being exposed to boiling water or steam. Then it became the custom to do here what had for some time been practiced in Europe, namely, to add plaster of Paris or fine ground gypsum to the extent of 1½ per cent. to 2 per cent. to the ground cement, which modified this phenomenon materially (Fig. 8) and produced a hydraulic substance of very desirable qualities.

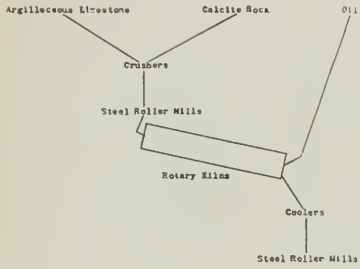

FIG. 7.—EARLY AMERICAN DRY PROCESS (ABOUT 1890.)

A little later, almost within the last twelve years, it was discovered that the raw materials must be very finely ground if you want to succeed in getting a perfect clinkering.

The wet method of the European works did good incorporating, and if you want that in the dry process and the quick-acting rotary kiln you must grind to an exceedingly great fineness. Also, if the cement is coarse it will hydrate slowly, with disastrous results of expansion. This was the heyday of the mechanical engineer.

These details of fine grinding had been neglected by the European practitioners of the art, but really explained their troubles. Their raw materials had been all right, because they had chalk and clay and it facilitated wet grinding. The incorporation was good, and the clinkering consequently was good, but their cement was frequently bad because it was coarse. Immediately a great variety of milling apparatus was invented and the American mechanical engineers worked hard upon this problem and with great success, and really the inventing and improving of this class of apparatus is still going on. The one kind of mill, modified, will serve for both raw and clinker grinding.

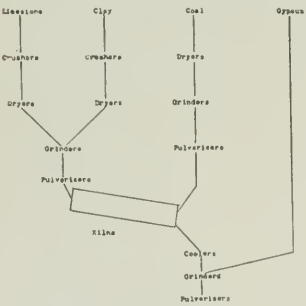

FIG. 8.—MODERN WORLD-WIDE PROCESS, DRY MATERIAL.

Two important classes of milling apparatus have been brought into use in this industry.

The development of flour milling when away from stone mills was towards steel roller mills, but in the cement industry the development of two important classes of comminuting apparatus resulted from the abandonment of stone mills. (It is true, stone mills are not yet entirely antiquated, for a new mill at Norfolk has just been equipped with everything of most modern form except the mills, which are burr-stones and which on experiment have proven to give satisfaction for the material operated on—marl—An interesting reversion!)

Of the new classes of mills referred to we have those of that type to which belong the Griffen, the Fuller and the Kent mills, in which revolving steel shoes or balls press against a steel die or channel. The Fuller, using balls, is highly efficient, particularly in producing a high percentage of the finest flour of cement.

The other type requires two separate installations, namely, a large drum lined with steel plates and partially filled with steel balls, to do the comminuting of rocks coming from the coarse grinders, and a long horizontal drum partly filled with large quartz balls, to do the pulverizing.

But the genius of Edison was now introduced upon the stage and in the first years of the century, after improving the large crushing machinery, he turned his attention to the improvement of the kilns. The prevailing length at this time was 60 ft., with an output of about 180 barrels per day and a

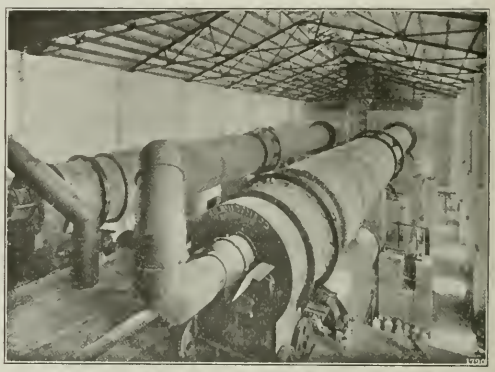

FIG. 8A.—ROTARY KILNS WITH ENLARGED BURNING ZONE AND COMPRESSED AIR FIRING AT THE WORKS OF NOERRESUNDBY PORTLAND CEMENT-FABRIK, NOERRESUNDBY, DENMARK.

coal consumption of 125 lb. per bbl. Some kilns 100 ft. long and 7 ft. diameter had been used in Europe on wet materials. Edison believed that if the kiln were 100 ft. long the product would be larger, the cement better and the coal consumption less. He has proven these points. But even with this economy the fuel consumption was three times the theoretical and twice what it should be practically. Immediately interest was centered upon the economics of fuel consumption in the Portland cement kiln.

It is admitted that the greatest avoidable loss is in the stack gases; next, the loss of radiation, and lastly, the heat carried off by the clinker. The last named has been most often attacked. Losses by radiation have been lately considered by inventors, but not yet successfully obviated, principally on account of the dilemma or choice between overheating the lining or overheating the shell. The losses in the stack gases have been diminished by careful attention to the details of burning, and lately it is believed by still further lengthening the kiln. One or two kilns here and some abroad, are said to be now operated experimentally on a length of 235 ft., more or less, but results are not divulged.

Strange to say, it is my belief that economies in coal, taken as a whole; that is, the coal for power and the coal for burning, will be improved by returning to the wet process. Before describing this I will speak of another process that marks an important epoch.

One of the greatest developments in Portland cement manufacture in this country has emanated from the steel works. Blast furnace slag, particularly when treated by water when hot, and then granulated, has many virtues for the aluminosilicate element in a hydraulic compound with lime. This was the old slag cement, but deserves no further mention in that

the composition and the reactions of that product are entirely different from Portland cement, belonging rather to the class puzzolana cement, with which Roman engineering accomplished much.

But investigators both here and abroad labored to produce clinker from a mixture of slag and limestone, and with the high heat of the rotary kiln they have been able to do it. It differs little from the standard process except that the slag is the clay element and is at once ready for pulverization, and except that Kent mills, together with air separators, are used for finishing. They have a thermal advantage, both in the fact that part of the lime has been calcined previous to their receiving it, and part of it is in favorable form of combination with the silica and alumina. Other advantages possessed by a steel works in making slag Portland cement are the credit for removing what is otherwise a costly nuisance and the important advantage of having blast furnace gas to utilize for the production of power.

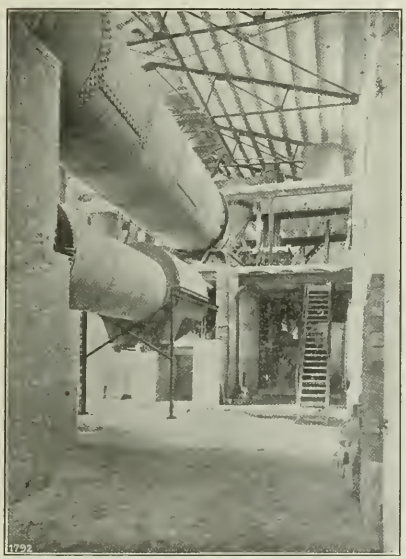

FIG. 8B.—ROTARY KILN OF NOERRESUNDBY PORTLAND CEMENT FABRIK, NOERRESUNDBY, DENMARK.

The Rotary Kilns are equipped with enlarged burning zone, compressed air firing and under coolers.

The manufacture of cement under these conditions is so favorable a proposition for the United States Steel Company that it is rapidly becoming the largest factor in the business. The environs of Chicago are producing almost as much cement as the whole of the Lehigh Valley.

Besides mixtures of clay and limestone, argillaceous limestone and pure limestone or calcite, slag and limestone, we have also as materials shale and limestone and clay and marl.

The shale and limestone introduce no complexity or important change from the type modern process except in the drying and grinding.

The marl, or what might be called *bog calcite*, has always been a different proposition. One of the important events which I have not previously mentioined, in the history of American Portland cement industry was the work of Millen and others in Central New York State, where such marls are plentiful. They struggled in the same way as Saylor and at the same time, and really manufactured on a commercial scale, but one by one succumbed to the competition of the Lehigh Vallley material. The latest to close, the Empire at Warners, N. Y., was a very important factor for some years, producing a good cement in rotary kilns, but under severe economic difficulties. Michigan suffered most from the false hopes held out of profit from her marl beds.

Now, it would seem strange to admit that wet marl costs too much to dry or to put in the kiln in a slurry, and then to claim that grinding into a semi-wet mix hard and almost dry rock and clay, or rock and shale, is a good economical proposition. Yet the truth of this is coming to be recognized.

A company operating in one of the Eastern States built a wet plant for limestone and clay quite some years ago, and although their handicaps were great they have succeeded by

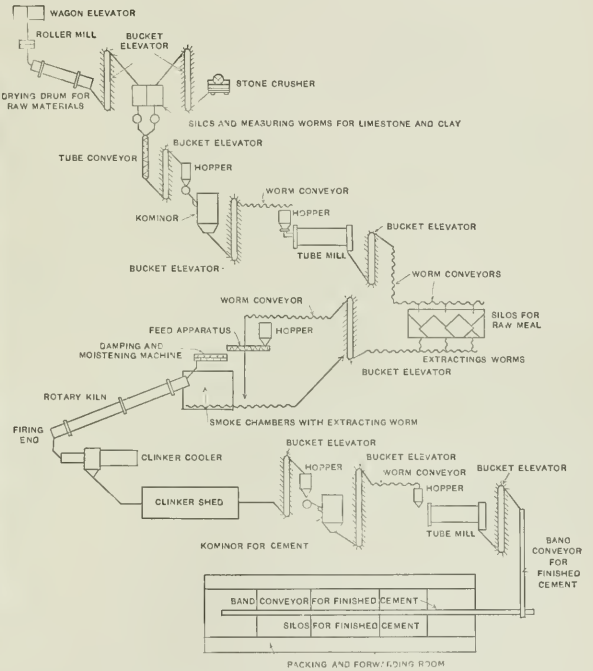

FIG. 9.—DIAGRAM OF MODERN CEMENT MANUFACTURE.

persistent effort at improvement and are about to obtain great aid from the introduction of the long kiln.

American cement engineering advanced beyond Europeon ten years ago—to-day European practice is in advance, and it is on account largely of improving in details on the American ways that most is promised from current practice in the wet way.

The explanation is this: The physical character of marl prevents the easy removal of water and also causes a slurry to carry too much water—almost 60 per cent.

The reason why wet processes failed was because no account was taken of this excess water even in the so-callled semi-wet slurry. When it was realized that this proportion of water should be cut down it was found that slurry with 40 per cent water could be pumped. But it was also found that a great deal depends upon the physical character of the raw constituents, and there are some, notably from hard materials, as limestone and shale, wherein 35 per cent to 32 per cent and even a little less may yet permit the free movement and carriage of the slurry. Great attention must be paid to

the fineness to succeed in attaining this minimum water. Thus you see the consumption of 200 lb. of coal formerly recorded against the rotary kiln in the wet method must be materially reduced. Then adopting the advantages of the long kiln for full utilization of heat and for large capacity whereby you also avoid coal for the dryer you come to a situation where a

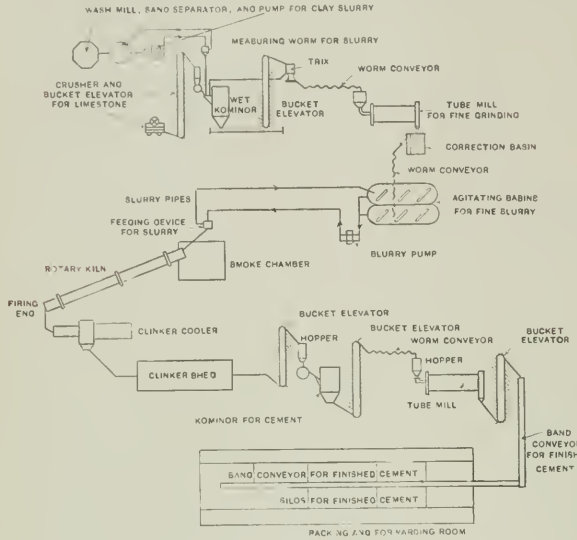

FIG. 10.—DIAGRAM OF MODERN CEMENT MANUFACTURE.

wet process for hard materials is not only feasible but highly desirable.

In most modern European mills there is provision for drying in rotary driers between the kiln and the stack and also for saving clinker heat by under coolers taking the air for combustion first over the clinker and closing up air leaks in the front of the kiln. (Figs. 8a and 8b.)

Then we have other factors which are important, and in these I believe a well-designed wet process introduces promise of saving. The first is raw grinding. With greater capacity of mills for equal horse-power we shall have made a gain.

It was admitted, when marl or chalk or clay were used, that the wet grinding was done at an advantage. It is so with the hard stone: after crushing, the pulverizing wet will be done more economically. In an experiment with the pebble mill of F. H. Smidth & Company the following results were obtained:

Fineness.

Residue on Sieve No. 180

13.0 per cent

8.0 per cent

Product.

Wet Grinding.	Dry Grinding.
Pebble weight	73 per cent of pebble weight
70 per cent of pebble weight	54 per cent of pebble weight

Secondly, it is safe to say that the fuel requirement in the kiln will be less by reason of the intimate contact of the particles of stone and clay—the rearrangement of the molecules in the clinkering stage will require less heat. This clinker also grinds more easily than that from less well compounded dry materials requiring high vitrification. Then there is no drier installation and no coal to be burned for it. There is no dust at the driers. The dust nuisance, in fact, is more than half eliminated in a wet mill. This is of considerable importance in reducing losses to machinery and the actual loss of the dust itself which carries with it the cost of royalty, quarry, drier and grinder and the nuisance to the neighborhood. The dusty appearance of the air around a group of cement mills is a joy to all interested in the industry as a sign of prosperity, but it is not pretty. We ought to pay dividends in esthetic currency whenever we can spare some—for outsiders.

This process has been placed on an economical basis by the advances made in the design and construction of rotary kilns which have been brought to such a point of perfection that it is possible to have wet mixtures containing between 30 per cent and 35 per cent of moisture with the same economy and to obtain the *same capacity* as can be had from modern rotary kilns on the dry process.

The following is the record of the performance of a kiln in a modern mill in Russia working the wet process on a slurry of 38 per cent water made from raw materials:

The kiln was 150 ft. long with enlarged burning zone from 6.9 ft. in diameter to 7.9 ft. in diameter. In 26 working days it produced 14,500 barrels of 380 lb. each, or about 560 barrels per day, with a coal consumption of 24.2 per cent, or about 92 lb. per barrel. This coal contained 1.42 per cent water, and on the dry basis had a heat value of 11,500 b.t.u.

Much advance is being made in the study of the heat economics of the kiln, and the researches of Newberry, Meade, Richardson and Landis are carrying us forward by placing more accurate data before us.

In good present dry practice, in kilns 135 ft. to 150 ft. long, we are producing 750 barrels of cement daily with a kiln coal

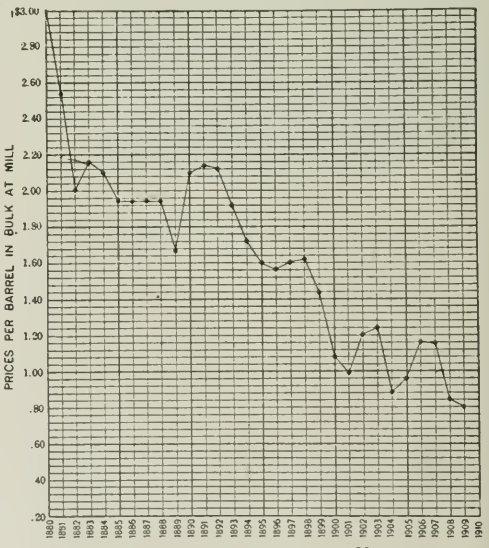

FIG. 11.—PRICE CURVE OF CEMENT FROM 1880 TO 1909.

consumption of 85 lb. The product is ground to 80 per cent fineness on the No. 200 sieve. Some mills are probably doing this at a mill cost of 60 cents. I have seen figures of some which indicate that 50 cents has been reached in the best

situated and best engineered plants, and that the given good installation could do this in a given good situation for coal and raw material. But the coal and the power draft are still the items promising improvement.

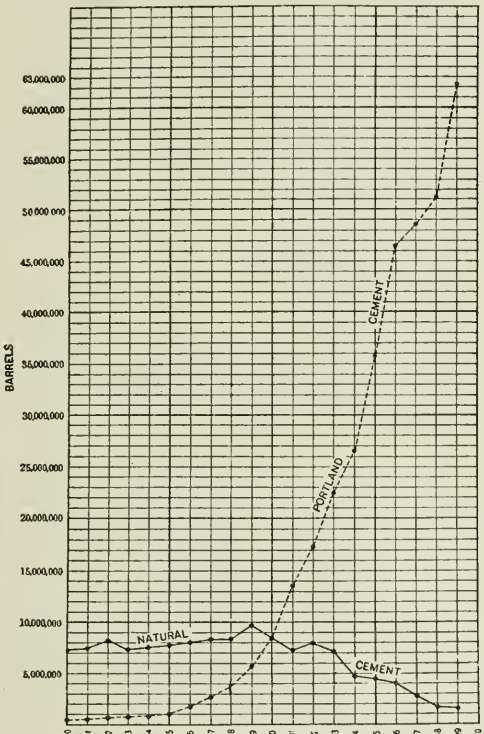

FIG. 12.—PRODUCTION CURVE OF PORTLAND AND NATURAL CEMENT.

As said before, power should be saved by wet grinding; it should be saved in grinding so-called wet-process clinker. Again, there is something promised in the way of a new discovery in pulverizing which will increase mill capacity very materially, it is claimed. This is the substitution in place of part of the usual charge of pebbles in the discharge end of the tube mill of some hard metal cylinders which, being separated from the pebbles by a screen, complete the pulverizing more perfectly and with less power.

The saving of heat from the clinker will improve in details of apparatus and considerably in efficiency. Professor Landis says that 10 lb. of coal are lost by heat of clinker, and that from 5 lb. to 7 lb. can be saved by efficient undercoolers. He has also made the important discovery that much more heat than we had suposed is generated by the formation of clinker. It is so large that in a theoretically perfect condition, with no losses, the reactions of the kiln would require only 15.7 lb. per barrel. With reasonable losses he thinks it ought to be run with four times this amount and maybe some day in some places with something like threefold that amount instead of sixfold, as we most often have it now.

Some are advocating dividing up the process again so that one kiln—perhaps the upright, which is so favorable for it in fuel economy—will be used for calcining and the more highly heated rotary for clinkering.

I have known this to succeed at one plant where the works were run economically on set kilns and rotaries. This was because the company had an excellent plant of old kilnsidle, and at a place where anthracite culm was cheap. The anterior burning of a mix of high and low limestone permitted them also to introduce the correction before entering the rotary.

I have said little of the power house and power transmission in speaking of these processes, but they have also had their natural stages of rapid evolution and improvement, as you all know. Electric driving, so much feared at first in the cement mill, has come to be universal.

By courtesy of Messrs. F. L. Smidth & Company, of Copenhagen and New York, I append sketch outlines (Figs. 9 and 10) which show a modern wet and a modern dry installation also which will give an excellent idea of the mechanical equipment and installation. It needs only the conception of the power house to complete the picture of modern cement manufacture in outline.

It is interesting now to notice from the statistics of the industry the influence of this evolutional development upon the prices of Portland cement.

As pointed out by Eckel, the important epochs in the history are plainly marked in the downward curve of price (Fig. 11), and the constant improvement in the economy of production is suggested in the form of the upward curve of production (Fig. 12).

It would be a very impressive reversion if a new drop in cost would be the result of studies of engineers leading to the use of water and a return to the wash-mill.

Metallurgical Notes.

Filter leaves are usually cleaned by soaking in a 10 per cent HCl solution, but this operation can be accomplished with a much weaker solution—2 or 3 per cent—if the solution is hot and delivered under a slight pressure into the center of the leaves. By forcing the hot solution through the pores of the cloth the lime is quickly dissolved.

Canvas slime tables have been built in various forms for the purpose of saving fine mineral escaping from concentrating works. One of the latest types is that devised by Mr. E. C. Porter at the Arizona Copper Company's concentrator at Morenci, Ariz. It consists of a dozen canvas tables arranged one above the other. The slime feed is allowed to run onto the tables until a coating of slime is formed, when the feed is shut off and a stream of water applied simultaneously to each deck by a traveling water pipe with suitable extensions over the several decks. When the accumulated slime is washed off the operation is repeated. The adaptation saves floor space and reduces the cost of attendance.

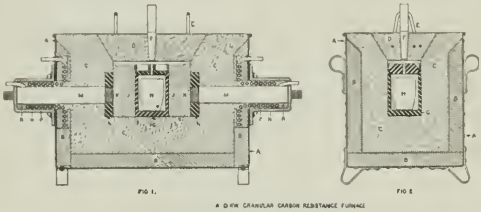
Grading Analyses.—In his reply to the critics of his paper on "Grading Analyses and Their Application," published in the *Journal* of the Chemical, Metallurgical and Mining Society of South Africa, Mr. H. Stadler states that an account of the laws of ore crushing and the experiments executed in that connection may be found in a work by F. Kick, entitled "Das Gesetz der proportionalen Widerstände und seine Anwendung," Leipzig, 1885. In further answer to those who object to the application of Kick's law in determining the mechanical efficiency of crushing machines, Mr. Stadler points out that, while perfectly homogeneous materials do not exist, nevertheless the definition of "equal technological state" is broad enough to include irregularities of the material so long as they are similarly distributed so that the average physical peculiarities of particles in different stages are identical. If these irregularities are, on the whole, similarly distributed, the calculations are not affected. He believes that Rand ore complies unusually well with the term "equal technological state" for the reason that it is composed of quartz pebbles of all sizes, embodied in a matrix which gives the same resistance to grinding as the pebbles

Granular Carbon Resistance Furnace.

By J. H. Goodwin.

Several workers have described laboratory furnaces using granular carbon resistors. O. P. Watts[1] suggested embedding in the granular carbon a graphite container for a working or removable crucible. The furnace here shown makes use of that scheme and it has some other details of construction that may be of interest.

As shown in section in Figs. 1 and 2 the furnace consists of a riveted sheet-steel shell, *A*, 17½-in. x 12¾-in. x 10⅝-in x No. 14 B. & S. gage, with feet and lugs of 1-in. x ⅛-in. band iron. Two 30-in. lengths of ¾-in. pipe slipped through the latter serve as convenient handles when it is desired to move the furnace. The shell is lined with magnesia-asbestos plates, *B*, 1 5/16 in. thick, inside of which is a thicker refractory lining, *C*, made by pouring in place a mortar composed of 8 parts of carborundum fire sand and 1 part of portland cement. The heating space is 7 in. x 5 in. x 3 in. and it is covered by a



FIGS. 1 AND 2.—DESIGN OF 10-KW GRANULAR CARBON RESISTANCE FURNACE.

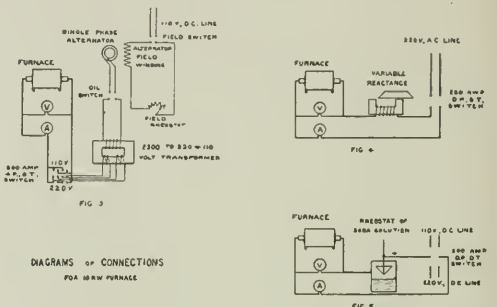
tapered block, *D*, of the same composition as the lining, containing an iron rod, *E*, for reinforcement and lifting and a hole, closed by a taper graphite plug, *F*, for watching through a cobalt glass the charge in the inner crucible. A 4¾-in. x 3-in. crucible, *G*, and cover, turned from Acheson graphite, occupy the center of the heating space and within this covered crucible a smaller graphite, magnesia or alumina crucible, *H*, containing the substance to be heated, is placed.

The electrodes are also of Acheson graphite. The plates, *L*, forming the ends of the heating space, are 4 in. x 3 in. x ¾ in. in size and they are firmly screwed on the 8¾-in. x 1½-in. rods, *M*, which fit loosely into the cylindrical part of spirals, *N*, of 5/16-in. copper tubing. The spirals in turn fit loosely into the brass terminals, *P*, attached with insulated bolts to the ends of the sheet-steel furnace shell. Good electrical connection between the brass terminals and graphite rods is obtained by sweating the latter in place with soft solder, *R*, which is kept cool during furnace runs by the circulation of water through the copper spirals connected by rubber tubing to the water supply and drain. Within the furnace shell the copper tubing is coiled in flat spirals in order to cool and protect the bolts and micanite insulation.

The resistor is composed of tightly tamped graphite, granular carbon or coke, *K*, ground to pass a 20-mesh sieve, and loosely added charcoal, *J*, crushed and collected between 4-mesh and 8-mesh sieves. For the first run some of the fine coke or carbon must be added to the charcoal, but after one heating this can be sifted out and the charcoal will then be of reduced resistance and the furnace can be started from 220 volts without any addition of carbon to the charcoal portion of the resistor.

With this type of furnace no electrode adjustment is possible, and, as the furnace resistance falls rapidly with increasing temperature a wide range of voltage control is essential. This can be obtained by a water rheostat, using sodium carbonate or hydrate to give sufficient conductivity, as shown in the diagram of circuits in Fig. 5, but such a method is every wasteful of energy and should not be employed if the furnace is to be used frequently. It is better to operate the furnace by alternating current and control the voltage by a variable reactance, as shown in Fig. 4, or, better still, to operate the furnace from a separate alternator of which one has the field control, as shown in Fig. 3.

The refractory lining of the furnace deteriorates and requires repairing from time to time. The resistor, outer crucible and cover burn slowly while the furnace is open to change inner crucibles, but making this time as short as possible a long life for these parts can be assured and they are easily replenished or replaced. The electrodes are not so easily replaced, but they do not need to be because they show very little deterioration, being always covered by carbon, which protects them from oxidation.



FIGS. 3, 4 AND 5.—DIAGRAMS OF CONNECTIONS FOR 10-KW FURNACE.

The furnace may be heated rapidly without injury. In one run, with a sample of platinum in the inner crucible, it was started cold with 200 amp at 200 volts. In three minutes the current had become 350 amp at 90 volts and the switch was thrown over to the 110-volt connection. Four minutes later the current was 250 amp at 70 volts and the sample of platinum was melted. Ten kw will maintain this temperature and crucibles may be heated and removed for pouring without interrupting the current or disturbing the outer crucible. The terminal cooling water carries off about 5 kw and the efficiency of the furnace is low, but for laboratory work this is compensated by the advantage of a durable, portable, compact, high-temperature unit that is not dismantled after each heat.

Fremont, Ohio.

[1] Electrochem. and Met. Ind., IV, 273.

Bakelite as an Insulator in Influence Machines.—Interesting information on the possibilities of bakelite and bakelized paper as an electric insulator is found in a recent German patent of Dr. H. Wommelsdorf for improvements in influence machines. In the past the discs, posts and other insulating portions of influence machines have always been made of glass or hard rubber. Both these materials have distinct disadvantages, the glass being breakable and the hard rubber becoming inefficient in time through electrical and chemical action. Dr. Wommelsdorf has now discovered that bakelite is suitable in a surprisingly effective manner for the manufacture of those parts of influence machines which are subject to the effect of the sparks and silent discharges and to the chemical action of the mixture of ozone and nitrogen oxide formed during the operation of the machine. Bakelite is very resistive against these influences. Moreover, by comparative tests the unexpected fact was established that influence machines, the inducing parts of which (for instance, disks) are made of this material, give an appreciably greater and almost double the quantity of electricity (coulombs) than influence machines of the same size and the same design with hard rubber disks. Bakelized paste-board is also suitable.

Heat Insulation of Furnace Walls.

By Carl Hering.

Although the fundamental principles concerning the losses of heat through the walls of furnaces are simple, yet it seems there still exists some doubt and uncertainty concerning rather elementary features, which in turn may lead to confusion, misleading statements and possibly even to positive errors.

The purpose of the present article is to endeavor to explain these general principles briefly from the standpoint of the practical engineer rather than from that of the academician, and to show how simple most of them are; also to point out some results and deductions which may be of practical value.

The analogy of a flow of heat through the walls of a furnace to that of a flow of electricity (a current) through a similarly shaped conductor are in some respects very close, and anyone familiar with the latter should not have any difficulty to understand the former. For instance, for the purposes of analogies only, suppose the inside of a cold furnace to be filled with mercury and the outside placed in a bath of mercury, all openings, of course, being closed; then by passing an electrical current from the metal in the inside to that on the outside, and measuring the voltage between the inside and outside, the electrical resistance of the walls as a whole could thereby be measured, supposing them to be sufficiently conducting. Or, knowing this resistance and the voltage, the current could be determined from them.

It will at once be seen that for any given dimensions and material of the walls, the greater the voltage the greater the current and vice versa. Hence, the voltage in that case is a direct measure of the current which leaks through. If, however, there are several furnaces, all of like dimensions but made of different materials, then the voltages for the different furnaces are no indication of the relative leakages of current, and to assume it to be so might lead one to very erroneous conclusions.

If, for instance, to take exaggerated cases in which the results require no refined calculations, the walls of three furnaces of like dimensions were made of copper, carbon and moist brick respectively, then with the same voltage for all three, the current would be enormously greater for the copper than for the carbon, and much greater for the carbon than for the moist brick. The voltage, being the same in all three, is, therefore, no indication whatsoever of the relative currents.

Now let the voltage be higher for the copper than for the carbon, the greater current will then correspond with the *greater* voltage. If, on the other hand, the voltage is greater, though not unreasonably so, for the brick than for the carbon, the greater current (namely, that in the carbon) will now correspond with the *lower* voltage; that is, just the reverse of the previous case. Hence, again, the current does not correspond with the voltage.

The same is true if a low voltage is applied to the copper and a somewhat higher one to the carbon, that is, just the reverse of the above case, yet the current for the copper would then still be the greater notwithstanding the fact that the voltage is now less. Finally, let the voltage for the brick be less than that for the carbon, the current through the brick will then still be less than for the carbon, although the relative amounts of the voltages are now the reverse of what they were above.

The conclusions from these exaggerated cases are so evident that no numerical calculations are necessary to further demonstrate them. In less exaggerated cases the difference is only one of degree, although specific cases might be selected in which the voltage might be made to appear to be a measure of the current, but if this were true as a general law, it would, of course, have to apply to all cases and it has been shown above that it does not.

The explanation, of course, is that the current is equal to the voltage divided by the resistance, hence the current depends quite as much on the resistance (hence on the material) as it does on the voltage; it is only when the resistance remains the same (namely, when the material and dimensions remain the same) that the voltage is a measure of the current.

This analogy to thermal flows is virtually a perfect one, as far as the subject now under consideration is concerned, namely, the insulation of the walls considered by themselves. The difference in temperature between the inside and outside surfaces is analogous to the difference in electrical potential, namely, the voltage; the thermal resistance (insulation) is analogous to the electrical resistance, and the flow of heat, or heat loss through the walls, is analogous to the flow of electrical current.

Hence by analogy, for any particular furnace (with fixed inside temperature), the higher the outside temperature (hence the less the drop), the less the loss, and vice versa. But in comparing furnaces made of different materials, whether of the same size or not, the outside temperature (assuming the inside temperature to be the same in all) is, as far as the walls by themselves are concerned, absolutely no indication whatsoever of the loss of heat—that is, of the insulation efficiency. The losses may be very different when the temperatures are the same, or they may be greater when the temperature is less, or less when it is greater. The loss depends not only on the temperature, but also on the total thermal resistance of the walls, and this in turn depends not only on the thermal conductivities, but also on the dimensions. But even for the same size, the outside temperature is no indication of the loss.

According to the thermal Ohm's law the flow in watts W is equal to the drop in temperature T in centigrade degrees divided by the thermal resistance R in thermal ohms.* Or $W = T/R$. Hence $T = WR$; that is, the drop of temperature in the walls is equal to the *product* of the flow and the resistance, but is not proportional to either alone unless the other is constant. If neither the flow nor the resistance is known, then the temperature is no indication of either, as for the *same* temperature in two cases W may be larger and R small, or the reverse; that is, the same temperature may be due in one case to a great flow through a small resistance and in another to a small flow through a great resistance.

Several numerical examples were given by the writer on page 125 of the March issue of this journal, hence they need not be repeated here.

The above applies to the insulation afforded by the furnace walls considered by themselves, as the heat insulator of the furnace, and as this is in almost all cases one of the two chief purposes of the walls it applies to the general case, and the principles enunciated above may be said to be the chief fundamental ones concerning the relations between the flow, the thermal resistance and the drop of temperature. It is, of course, assumed herein that all the heat reaching the outside surface is freely dissipated as fast as it gets there and without any obstruction to such dissipation; the effect of such possible obstruction will be considered later.

Besides these fundamental considerations there are some minor or less important ones, just as is the case in most other problems, and they modify the general results somewhat. They are of more interest to the academician than to the practicing engineer. To include them in calculations may be said to be a refinement, or a second approximation, as it is often called; but in most furnace calculations which the engineer has to make, and which are necessarily somewhat crude in the present state of our knowledge or lack of knowledge of the physical properties of the materials involved, these minor features may generally be neglected or allowed for as correction factors instead of attaching the same importance to them as to the fundamental ones, whereby the problems would often be hopelessly complicated. Among these may be mentioned the

*For the definition of a thermal ohm see the article on this subject in the January issue of this Journal, p. 13. (Article on thermal resistance and conductance; the therman ohm and thermal mho.)

temperature coefficient of the thermal resistance, and the further variation of this coefficient with the temperature. This will undoubtedly effect the results somewhat, from the academician's standpoint, and will afford him the means of making the formulas and analyses very complicated, while in their unburdened or fundamental form they are very simple and easily understood. Moreover, as our knowledge of the numerical values of the resistivities or conductivities themselves is to-day still in a somewhat crude state it seems unreasonable to lay much stress at present on any refinements of these values. If the engineer has given to him reasonably reliable values for the usual materials when hot and when cold, it will suffice for most of his purposes and it will generally not be necessary for him to complicate the analytical work with the introduction of temperature coefficients.

Another one of these less important features, which, in the opinion of the writer, are best considered as secondary ones, to be introduced as corrections rather than being given the importance of a fundamental feature—is the rate of dissipation of heat from the outside of the furnace to the air or water jacket when this dissipation is restricted as distinguished from being virtually free and unlimited, as it would be with a good water jacket, and as it was assumed to be in discussing the fundamental relations above. If the outside surface is large enough or sufficiently exposed to draughts or water circulation to dissipate all the escaping heat freely so as not to bank it up, then the resistance which the flow of heat meets at this surface may be neglected; or it may be roughly allowed for on the basis that for a given kind of surface and a fixed room or cooling water temperature the greater the heat dissipated per square foot the higher will be the temperature which that surface will assume. With restricted dissipation that temperature will, of course, be higher, but in either case the rise will not be nearly as fast as the increase of the heat dissipated per square foot; according to Stephan's law the radiation varies with the fourth power of the temperature (absolute scale). hence to dissipate a considerably greater amount of heat by radiation would involve only a relatively small rise in temperature of the surface.

While, therefore, it is undoubtedly a fact that theoretically the temperature of a given surface will increase when the amount of energy dissipated from it increases, yet the obstruction to the heat flow which causes this appears to be too small relatively to the resistance of the walls to be given much importance; the wall insulation is the important one, the other is of only secondary importance. If, for instance, the fall of temperature from the inside to the outside of the wall is a drop from 1800° to 118° (see example below), namely, 1682°, and that from the outside (118°) to the air at 20° is 98°, the walls will, as an insulator, be more than 18 times as important as the superficial resistance to dissipation; the latter is in this case only 5.5 per cent of the total effective resistance, and it is, therefore, certainly of only secondary importance

In this connection, however, attention might be called to the advantages of treating or covering the outside surface of the walls to obstruct and hinder as much as possible the dissipation of heat from it, as could be done for low temperatures by a thin layer of cork, for instance. This would increase the insulation efficiency, or for the same efficiency, would reduce the thickness of the wall required for insulation; the hotter the outside of the wall of a given furnace, the less the heat loss through that wall. But in that case this outside coating must, of course, be able to withstand that higher temperature when exposed as it is to the free oxidizing influence of the hot air

If it were possible to find some coating for the outside of a furnace which would resist the dissipation of heat to so great an extent as to form a sufficient insulation of the furnace, then the insulation afforded by the walls might be neglected and the walls made as thin as other considerations would permit. In that case the lower the temperature just outside of this wall, the less the heat loss. But this is, apparently, more of theoretical than of practical interest, as at present the chief insulation is afforded by the body of the furnace wall.

Theoretically the temperature which the outside surface of a furnace will naturally assume when the dissipation from that surface is appreciably restricted, that is, when it is not free and unlimited, is that at which the heat flow to which the dissipation from that surface is restricted, is exactly equal to the flow reaching it through the walls; this is the stable state and the temperature will rise or fall until that state is reached. For a given furnace with a given inside temperature and with restricted dissipation from the outside, the higher the temperature of the outside surface the less will be the flow through the walls, but the greater will be the dissipation of heat from the surface; hence, as the one diminishes while the other increases, the stable state is reached more quickly and the changes of temperature corresponding to changes in flow are necessarily less than they would be for either alone or if both changes were in the same direction.

As was shown above, the resistance due to this restricted superficial dissipation is of relatively small importance compared with that offered by the walls, and the temperature rise which it produces is, therefore, probably of more interest to the academician than to the engineer. Moreover, that so-called stable temperature is so greatly dependent upon the surrounding temperature, hence on the weather and the seasons, as well as on draughts, the temperature of nearby objects, the presence or absence of nearby walls or other objects, etc., that no great importance can be attached to it.

As a recent statement, however, attaches sufficient importance to this outside temperature to recommend it as a "very good" means for measuring the losses of heat through different furnaces and for comparing the losses and the efficiency of the material of the walls, the writer has made the following approximate analysis of the relations, not because he considers it of much importance, but because the question was raised.

To treat it analytically involves very troublesome equations of the fourth degree. Moreover, the laws concerning the convection of heat from surfaces are complicated and involved if at all definite. But to solve this problem in this way one would express the heat flow through the walls algebraically in terms of the unknown outside temperature, then express that dissipated from the outside by radiation and convection in terms of this outside temperature also. The flow is, of course, the same in both and so is the outside temperature. Hence this gives two equations with two unknowns, and they can, therefore, be solved for both. The result seems to be of too little interest to warant the labor.

The engineer is usually satisfied when he knows that such a result is not of much importance, and this can be shown by means of a simple graphical method applied to the following actual numerical cases.

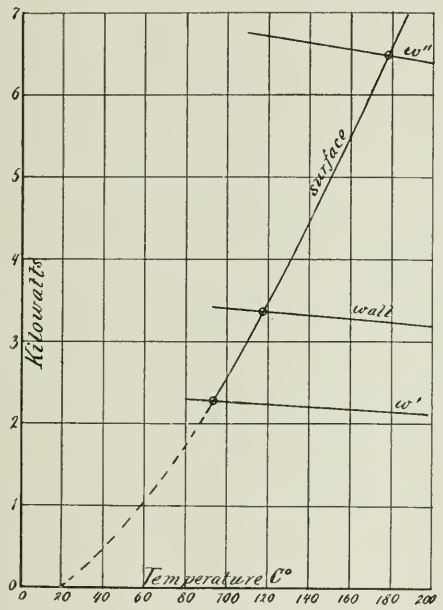
The following dimensions and data have been chosen to simplify the calculations rather than to serve as an example of a good design; also chiefly in order to adapt them to the small range of the available data, given in the very convenient curves of Mr. Snyder, for the sum of the radiation and convection losses from the surface of bricks to the air at various temperatures, as given in the *Transactions* of the American Electrochemical Society, Vol. 18, 1910, page 239. The writer here assumes their correctness, as he has not confirmed them.

Assume a furnace of silica brick; inside dimensions 6 in. x 6 in. x 6 in.; thickness of walls, 9 in.; hence outside dimension 24 in. x 24 in. x 24 in.; inside temperature, 1800° C.; room temperature, 20° C.; thermal resistivity of silica brick, about 48 thermal ohms. Hence inside surface is 216 sq. in.; outside, 3460 sq. in. = 24 sq. ft.; the mean (geometric) cross-section perpendicular to the flow is the square root of $216 \times 3460 = 866$ sq. in.; hence the total thermal resistance is $48 \times 9 \div 866 = 0.50$ thermal ohm. The graphical solution consists in calculating by means of the well-known formula

watts = drop in temperature ÷ resistance in thermal ohms.

the flow through the walls for each of several assumed temperatures of the outside of the walls; then plotting them as shown in the adjoining figure and drawing a curve through them, this curve is marked "walls," representing the part which the walls take in determining the total loss. It will be seen that this line is nearly horizontal, showing that the loss is nearly the same for all of these outside temperatures, hence nearly independent of them. Under such circumstances it would be very poor practice to measure the flow by means of these small differences of temperature.

Then calculate for each of those same assumed temperatures of the outside of the walls, the flow of heat in kilowatts which will be dissipated from the 24 sq. ft. of outside surface by multiplying that surface by the constants for each of those temperatures, obtained from Mr. Snyder's curves, on the assumption that they are virtually the same for silica brick as for firebrick. The results when plotted are shown in the curve



HEAT CONDUCTION THROUGH FURNACE WALLS.

marked "surface." It will be noticed that this curve is very steep, which means that this temperature varies only slightly for a very large variation of the flow. That is, the flows are not greatly dependent upon those temperatures. Hence for this reason also it would not be good practice to measure the former by means of the latter.

It is evident that the stable state will be reached when the temperatures for each of the two curves are equal, hence the desired value is at the point of intersection of the two curves at which, of course, the flows are also equal. Hence in this case the outside stable temperature will be about 118° C. and the loss of heat about 3.35 kw.

As remarked above, this temperature is a very unreliable figure as it depends on the weather, draughts, etc., and, in the opinion of the writer, would for that reason alone be unfit to be taken as even an approximate measure of the relative losses or of the relative insulating values of different wall materials. But to show that it would be a poor figure to use as a measure for comparing different wall materials, even under very carefully maintained laboratory conditions, hence even for the academician, two more curves have been calculated, one marked w' for a material having a resistance 50 per cent greater, namely, 0.75 thermal ohm, hence probably greater than any suitable material would have, and the other, w'', for one having a resistance 50 per cent less, namely, 0.25 ohm, hence half as great as the original one and extremely low. These three examples, therefore, cover very wide ranges.

It will be seen that the stable temperature for w' will be about 94°, hence only 24° less, although the difference between the two materials as insulators is quite great, namely, 50 per cent, and although the relative losses are reduced from 3.35 kw to 2.3 kw, hence also quite a great difference.

The former loss is very nearly 50 per cent greater than the latter, which shows that the total loss is determined almost entirely by the resistivity of the wall material and that the slight change in outside temperature is of practically no importance in determining the flow or loss and may, therefore, safely be neglected.

The results for the curve w'' are similar. The stable temperature then will be 178°, or only 60° higher, although the material is only half as good an insulator as the original. The flow, 6.5 kw, is very nearly double the original, showing again that the resistance of the wall material is decidedly the governing factor for determining the flow and that the outside temperature may safely be neglected, except that one must, of course, expect a somewhat higher outside temperature when the flow is considerably greater.

This analysis shows that the curve marked "surface" is very steep as compared with the others, which means that as far as the surface dissipation is concerned only a few degrees rise (horizontal distances) will cause the surface to dissipate very much more heat (vertical distances). Hence to determine the flow by means of this temperature is like determining the movement of the long end of a lever by a crude measurement made at the short end; a very small error in the measurement will give rise to a very large one in the result that one is striving to get.

To measure such temperatures accurately on the outside wall of a furnace and to expect to get concordant results would, in the writer's opinion, be a hopeless task; they would probably differ by 50 per cent on different parts of the same furnace at the same moment. And even if a mean of such very unequal readings had any value as such, it would be of little use because we know too little about the constants for the dissipation of heat from surfaces, and, therefore, could not intelligently interpret the temperature in terms of resistances or losses even if the values of the temperature were accurate.

There is still another feature involved in this question of heat insulation which may also not be clearly understood and which is of greater importance. It bears on what might be called "over insulation." In this feature the electrical analogy misleads one instead of helping one.

Regret has often been expressed that nature has given us no practically perfect heat insulator (other than a vacuum), such as rubber is as an electrical insulator. This is not so serious, however, because in the very cases in which it would be most desirable, namely, for high-temperature furnaces, such an insulator could not be used even if it existed.

Suppose, for instance, a furnace was surrounded by a vacuum, which is the most perfect heat insulator known. A vacuum insulates only against convection of heat, but not against radiation, as we know, because we get our heat from the sun through a vacuum: but in the present argument the radiated heat is considered zero by the assumption of a perfect insulator.

In such a furnace the heat will at first flow toward the outside; as it meets with the vacuum it can go no further, hence will accumulate and it will continue to do so until the outside is at the same temperature as the inside. This, therefore, means that the walls of the furnace will throughout their whole thickness reach exactly the same temperature as the inside of the

furnace, and for high-temperature furnaces this means that the whole furnace would soften and melt. Hence a perfect insulator could not be used even if it existed. Some flow of heat must, therefore, be allowed for in order to keep the walls from melting; the problem is to find the least possible amount which will still do this. This much-desired perfect heat insulator around the cylinder of a gas engine, for instance, would be fatal to the cylinder.

Again it might be argued, why not surround the outside of a furnace with cotton, mineral wool, very fine magnesia or some similar material which has a very high thermal resistance due to its holding air in its pores so that the air cannot move, still air being one of the best insulators.

The same reasoning as above will show that in such a case the outside of the bricks, where the outflow of heat nearly ceases, would soon become very highly heated and unless they and the outside porous insulator can stand this high temperature the furnace would fail.

It has no doubt often happened that parts of furnaces have thus been melted away due to over insulation, when such melting might have been prevented by allowing a greater heat flow to pass through those parts by insulating them less. Too great an economy of heat loss may result in other more serious losses; a good thing may be overdone; the loss of a furnace wall may be much more expensive than the loss of some heat.

One of the cheapest and best insulators seems to be a joint. Hence, for good insulation the bricks should, if practicable, be laid dry and so that their flat sides are perpendicular to the flow of heat, as this gives the maximum number of joints in the path of the flow. But, as described above, this might result in the melting of the inside layer of bricks, hence it should be done cautiously.

Of course, whenever the maximum temperature of the furnace is never high enough to soften the brick, then over-insulation need not be feared.

Philadelphia, Pa.

Notes on Cripple Creek Mill Practice.

Editorial Correspondence.

The interest which, for the past two years, has centered in the cyanidation of Cripple Creek raw ore will not abate much this year. In fact it is more likely to increase for the reason that we do not yet know the chemical details of one of the processes used, and further, that a wholly new principle is to be applied this year in a new mill now building. The successes of 1909 and 1910 will be followed, we hope, by still another in 1911, and the field for local treatment of Cripple Creek ores be thereby greatly enlarged. It seems certain even now that the list of metallurgical failures at Cripple Creek will not be added to if intelligence is displayed by those who direct future ventures.

At the present writing the secret of success is told in a few words—ordinary cyanidation assisted by preliminary concentration and the application of cheap chemicals with the cyanide. The object of the concentration is to remove a small quantity of refractory mineral, the retention of which would only increase the time of extraction of the whole mass, or possibly defeat the whole process. The comparatively small quantity of the ore thus removed can be sold to smelters or given such special treatment as it requires. But the prospect now is that even this step will be rendered unnecessary by the Clancy process which will be in operation in a few months.

Stratton's Independence Mill.

The method of treatment used in this mill was worked out by Mr. Philip Argall after many years' experience with the cyanide process and Cripple Creek ores. Based on experiments made at a much earlier date, the plant finally was put in operation in April, 1909, after some unavoidable delays and in spite of the unfavorable criticism of doubting Thomases. The problem was to treat at a profit a large dump of low-grade ore, amounting to almost 1,000,000 tons, which had accumulated for many years. The average value of the dump was determined by extensive sampling to be $3.80 per ton. This figure is much lower than the cost of treatment at some of the earlier mills and is even less than the lowest treatment rate now offered by custom mills on low grade Cripple Creek ores, viz., $4 per ton. That the cost of treating this dump in the Independence mill is about $1.50 per ton is evidence of the general improvement in milling methods and of the ability of the technical staff in charge of the work. The mill was the first successful cyanide plant treating sulpho-telluride ores in the Cripple Creek district, although several successes had been scored previously in cyaniding the oxidized ores. It has been steadily enlarged since beginning operations from an original capacity of 4500 tons per month to practically more than 9000 tons per month at the present time.

Crushing and Grinding.—The dump ore is mined by electric shovel, loaded into 4-ton cars and hauled up an incline to the coarse crushing plant. Two cars are in use, one being loaded while the other is dumping. In this way a car is loaded and dumped about every three minutes, which permits crushing a day's run of 300 tons for the mill in about four hours. The cars are dumped directly over a 7½ D Gates gyratory crusher which reduces the ore to 4-in. size. The crushed ore is discharged over a grizzly with 2-in. openings, the oversize falling onto a picking belt where pieces of steel and wood are removed. The belt discharges into a 5 K Gates gyratory which crushes the ore to 1½-in. size. The product of the second gyratory is combined with the undersize of the grizzly and elevated by a belt conveyor to the storage bin in the concentrator building.

The design of the storage bin and feeder insures a positive steady feed of ore. The bin is circular with conical bottom, the cone terminating in an opening 6 ft. in diameter, through which the ore feeds into an open cone about 12 ft. in diameter at the top and placed with its upper openings in the same horizontal plane with the 6-ft. opening of the main bin. The lower cone terminates in an opening about 12 in. in diameter, through which the ore is discharged by a revolving table feeder. By this construction the ore flows freely and the bin may be completely emptied without extra attention.

The method of adding lime for protective alkalinity differs from the usual practice of adding it in a solution form. As the ore leaves the storage bin it is moistened with a small quantity of mill solution, which settles dust and slakes the solid lime, which is added continuously at the rate of about 1000 lb. for the day's run of 300 tons of ore. This gives a protective alkalinity in the solution of .002 per cent. The mixed ore and lime are then elevated to bins above the rolls, and further reduced in two successive sets of rolls to ⅜-in. size. This material, which constitutes the Chilean mill feed, is then elevated and distributed to three bins, one for each mill. The Chileans are of the fast running type, 6 ft. in diameter, making 33 r.p.m. They grind in mill solution which is kept at a strength of about ½ lb. KCN per ton and discharge through 12-mesh screens. The capacity is about 100 tons of ore each per 24 hours, 60 per cent of the pulp passing 150-mesh screen.

Classification.—Sand and slime are classified prior to concentration in two spiral classifiers, each of 300 tons daily capacity. The sand is delivered 5 ft. above the feeding point, carrying from 4 per cent to 7 per cent slime, depending on the varying nature of the ore. The slime emerges 6 in. below the feeding point, carrying about 3 per cent of sand coarser than 150-mesh.

Sand Concentration.—Mill solution is added to the sand as it leaves the classifier, and the pulp is distributed to 20 Card tables. Two grades of concentrate are obtained, the first carrying about 5 oz. gold per ton, which is shipped to the smelter; the second with about 0.75 oz. gold, which is sold to

chlorination works. The Card table is preferred for this work as it gives a cleaner division between the two classes of concentrate and a consequent financial advantage in their disposition. The sand tailing is laundered to a sump and delivered by centrifugal pump to the cyanide plant for further treatment.

The coarser and heavier sand is separated by spitzlutten and reground in a tube mill. The reground pulp is classified by cones into sand and slime, the former being treated on two Card tables and the latter on four Deister slimers. All of these tables produce first and second grade concentrates.

Slime Concentration.—The slime from the classifiers is thickened in 16 8-ft cones. The underflow is distributed to 10 Deister slime tables and four vanners. Like the Card tables, the Deisters make two grades of concentrate, the first carrying about 7 oz. gold per ton and the second from 0.50 oz. to 0.70 oz. The total concentrate removed by sand and slime treatment amounts to about 3 per cent by weight of the ore treated and contains 40 per cent of its value. The tailing from the Deisters and vanners is laundered to a sump which also receives the overflow from the thickening cones and the tailing from the tables treating reground sand. A centrifugal pump returns the slime to the cyanide plant for further treatment.

Cyanide Treatment.—The regular cyanide treatment is supplemented by the use of bromo-cyanogen. The sand and slime pumped from the concentrator are delivered to the head of the cyanide mill where they are reclassified. The sand is discharged to a reciprocating conveyer which distributes to six sand filter bins, each of 250 tons capacity. The sand enters the bins with an assay value of 0.06 oz. to 0.08 oz. gold per ton and is discharged, after treatment, with 0.03 oz. to 0.04 oz. The treatment is as follows: After a bin is filled and drained it is leached with solution strengthened by the addition of 25 lb. KCN to each bin. When this solution has filtered the sand is given successive washes with barren solution and water and sluiced out.

The slime from the classifiers flows to four large settling tanks, the overflow from which is usually returned to mill solution storage. It is the intention to keep the mill solution at a strength of ½ lb. KCN and at a value not exceeding $0.50 per ton. When this is exceeded the tanks are not allowed to overflow, but are decanted to the precipitating department. The thick settled slime is drawn from the bottom of any one or all of the tanks and pumped to the agitator for 10 hours agitation, with air at 30 lb. pressure. A charge consists of from 75 to 100 tons of dry slime and from one and one-half to two times that amount of solution. Thirty lb. KCN are added to each charge. The agitation tanks are modified from the standard construction in air agitators by shortening the central tube one-half, thereby securing the full benefit of the air in agitating the pulp in the upper half of the tank. After 10 hours' agitation the charge is pumped to a second agitator for special chemical treatment.

Filtration.—The vacuum filter is of peculiar construction, generally according to the Cassell type, and consists of 110 leaves 7.5 ft x 6 ft. The capacity is sufficient to handle the contents of an agitation tank in seven or eight charges in 24 hours, three hours being the time required for a complete cycle of loading, washing and discharging. Vacuum is maintained at 10-12 in., which is practically the best obtainable in slime filtration at the altitude of 10,000 ft., where the barometer normally stands at about 20 in.

Precipitation.—The filtered gold solution is clarified in two Johnson presses and flows to the zinc boxes for precipitation. The daily tonnage of solution precipitated is about 350 tons, or little more than the tonnage of ore treated. Occasionally, when the mill solution rises too high in value, several hundred tons may be precipitated in addition to the regular quantity.

The gold precipitate receives the usual acid treatment and is discharged to a pressure tank connected with a small filter press. The press cake is dried, roasted and ground in a small tube mill using pieces of shafting for the grinding medium. The object of the last step is to put the precipitate into as uniform condition as possible so that an accurate sample can be taken. Prior to the introduction of this practice a great deal of time was consumed in making settlement with the smelter on account of the variation of the sample taken for assay.

The Independence mill was erected at a cost of over a quarter of a million dollars. The preliminary experiments indicated that a fair profit could be made by the treatment of 10,000 tons per month, and it is interesting to know that the actual working costs have checked the estimates remarkably close. No official figures have yet been given by the company, so that details of costs and profits are not actually known to the public, but it is stated that operations are being conducted at a satisfactory profit.

The mill is equipped with duplicate pieces of machinery at those points where a break would interfere seriously with continuous operation. Cement floors, launders and sumps effectually prevent the loss of valuable cyanide solution and contribute to the cleanliness of the plant. Crushing and concentrating in cyanide solution, which was one of the features concerning which skeptics expressed their doubts, has not given rise to any trouble, either by serious loss of solution or by ill effects on the workmen. Altogether the plant has been a success on which the company and staff are to be congratulated.

Following is a condensed statement of the flow of ore through the mill:

Ore from dump in 4-ton cars, to 1.

1—7½ D Gates gyratory, discharging to 2.

2—Grizzly; oversize to picking belt, thence to 3; undersize to 4.

3—5K GGates gyratory, discharging to 4.

4—Incline belt conveyer to 5.

5—Mill storage tank; lime and a small quantity of mill solution are added to the discharge and the mixture elevated to bins, thence to 6.

6—Two sets of rolls; product elevated to bins, thence to 7.

7—Three 6-ft. Chilean mills, 12-mesh screen; discharge to 8.

8—Screw classifiers; sand to 9, slime to 14.

9—Distributor to 20 Card tables; high grade concentrate to smelter and low grade to chlorination mill; tailing to 10.

10—Sand tailing sump; centrifugal pump to cyanide department, 17. Coarsest sand reground in tube mill; product to 11.

11—Two classifying cones; underflow to 12, overflow to 13.

12—Two Card tables; concentrate shipped, tailing to 16.

13—Four Desiter slime tables; concentrate shipped, tailing to 16.

14—Sixteen thickening cones; underflow to 15, overflow to 16.

15—Ten Deister tables and four vanners; concentrate shipped and tailing to 16.

16—Slime tailing sump; centrifugal pump to cyanide department, 17.

17—Cyanide mill; screw classifiers; sand to 18, slime to 19.

18—Sand leaching tanks; filtrate to 23, sand discharged.

19—Four settling tanks; overflow to mill solution or to 23; thickened pulp to 20.

20—Agitating tank for 10 hours; thence to second agitator for special chemical treatment for six hours, thence to 21.

21—Storage tank for filters, to 22.

22—Vacuum filter; gold solution to 23, slime to discharge

23—Two Johnson clarifying presses, to 24.

24—Seven zinc boxes; barren solution to mill storage; precipitate to acid tank and filter press. Press cake dried, roasted, pulverized, sampled and shipped to smelter.

The Colburn Mill.

The latest development in the local treatment of ore at Cripple Creek is the decision of Mr. E. A. Colburn, principal owner of the Ajax mine, to erect a mill embodying the much discussed Clancy cyanide process. This will be the first commercial application of the Clancy principles and the outcome

will be awaited with great interest. Metallurgists generally are favorably impressed with the principles of the process and earnestly hope that the first installation will successfully meet the prime requisite of making money.

The Colburn mill, as it is to be known, is being erected near the Ajax shaft, above the town of Victor. Both mine and dump ore will be treated. The plant will comprise two principal buildings, one for crushing and sampling and the other for cyanide treatment. The excavations have been made, concrete foundations put in and it is expected that the plant will be in operation this summer, probably in June.

An aerial cableway will be installed for transporting ore from the dump to the sampler, while mine ore will be delivered from the shaft by electric tramway. The sampler will have a capacity of 100 tons in eight hours and will have to be run two shifts to supply the cyanide plant, the capacity of which will be 200 tons in 24 hours.

The sampler will be arranged for the separate treatment of leasers' and company ore. Coarse crushing will be done in a Symons gyratory, the product from which will be elevated and diverted to steel bins. One of the latter will be a scale hopper bin for leasers' ore and the other an ordinary bin for company use. From these bins the ore will be elevated to the roll and screen system. The sample will be taken by two Snyder samplers when the ore is reduced to ¼-mesh. The final roll product will be reduced to 12-mesh and elevated by belt conveyer to the cyanide plant. An exhaust dust collecting system will gather the dust from various parts of the sampler and conduct it to a settling chamber with hopper bottom, from which it can be drawn onto the conveyer belt and sent with the ore to the mill.

At the head of the cyanide mill will be three grinding and classifying units, each consisting of a storage bin for crushed ore, a classifier and a tube mill. The bins will be circular in form, built of steel, with bottoms of rock and cement sloping at an angle of 45°. The ore will flow from the bins into the classifiers, which will be of the spiral vane form. The slime will overflow to the agitators and the sand will be ground in tube mills. The tubes will be of a shorter type than customary, 5 ft. x 16 ft., and will have El Oro lining and screw feed. They will grind in closed circuit, their discharge being returned to the classifiers.

The air agitators will be of special construction, suited to the application of electrolysis as well as of agitation. The form will be circular, with cone bottom, and the ratio of height to diameter of the circular portion will be 1:1. The central air tube will be about half the height of the tank, so that the pulp in the upper half of the tank will be thoroughly agitated by the air rising from the central tube.

The agitators will be fitted with electrodes for the application of the electric current during agitation, both for extraction of the gold from the ore and for regeneration of the cyanide solution. The cathode will be in the form of iron sheets suspended in the pulp around the inner periphery of the tank, and the anode of fused ferric oxide suspended near the center. There will be five of these tanks, which will be used for storage as well as for agitation.

The Moore vacuum filtration system will be used. On account of the location of the mill with respect to the town of Victor and adjacent mining property it will not be possible to discharge the slime tailing by sluicing. An automatic system of stacking the tailing on the dump is now being worked out whereby the tailing will be removed from the Moore tank by a screw conveyer and delivered into a hopper. From the hopper it will be carried by bucket tramway to the dump. It is planned to make the loading and dumping automatic and to have the bucket dump at a series of different points on successive trips.

The Merrill system of zinc dust precipitation will be installed and the gold refined at the mill.

The plans contemplate a mill as nearly automatic in operation as possible, with a minimum labor requirement. It is expected that two men for each of two shifts in the sampler and two for each of three shifts in the mill, in addition to the superintendent and chemist, will be sufficient. The mill design and construction is under the direction of S. A. Worcester and the metallurgical details are being worked out by A. W. Warwick.

Essential Points in the Management of a Chemical Industry.

By John Woods Beckman.

In every chemical industry the "chemical control" and the "chemical balance sheet" are two fundamental points which demand the closest attention. They are the backbone. Without them no chemical industry can be carried on successfully nor can the fullest return from the investment in the plant be expected.[1]

"Chemical control" is understood in a general way to mean not only the absolute knowledge, on the part of the factory managers, of the chemical constituents in the raw materials that enter the factory at one end and the finished product leaving at the other end, but the "chemical control" involves the chemical knowledge of each individual step in the whole process.

Naturally the chemical control is distinctly a chemical question, and is in the special charge of the chemical engineer at the plant, and to do the chemical work it necessitates the equipping of a first-class laboratory, with an outfit well adapted to accurate, quick routine work, as well as offering the possibility of carrying out the most complicated analysis and doing some research work. The laboratory and its staff of men and boys are the tools for the efficient carrying out of the chemical control, and the control can only be carried out in conjunction with the laboratory. On this account the chemical staff can not be too well selected, as it is the heart and brain combined of the factory.

A great number of analyses of more or less importance have to be turned out daily by the laboratory. The most important ones are the determinations made of the incoming raw materials, which cannot be given too much care. The importance of these determinations is twofold, being based on financial reasons as well as on factory-operation reasons.

The raw materials purchased, or credited to the factory, have to come up to contracted for or specified contents, and the only guide as to the accuracy of the bills presented is a most careful determination of percental composition of the raw materials.

With this knowledge at hand of the incoming raw materials it is possible for the chemical engineer to arrange the process accordingly, but of almost equal importance is the knowledge of the actual amounts of every small unavoidable admixture occurring in the raw materials. These are often the makers or the spoilers of a process, and on this account it is of vital importance to the industry that the raw material analysis be carried out to the utmost completion, even having the "traces" determined.

Catalytic action is more and more being appreciated in the carrying out of a chemical process, and Ostwald says that "there is probably no kind of chemical reaction which can not be influenced catalytically, and there is no substance, element or compound, which can not act as a catalyzer," and his words are being verified each day. Many are the chemical industries that have stumbled and fallen for unexplainable reasons which could have been remedied if a complete knowledge had been available of all the ingredients of the raw materials.

As is well known there are catalytic agents which assist the chemical reaction, while there are such which produce opposite phenomena, called negative catalysis, retarding and upsetting

[1] In this article no mention is made of the management of financial matters nor of labor.

the normal course of the chemical reaction. With a fair knowledge of the catalytic phenomena, and with a complete knowledge of the constituents of the raw materials, it is possible for the chemist very often to remove stumbling blocks in the factory, and again improve conditions by some small addition of a foreign substance to act as a catalytic agent. The only safe way that makes it possible to improve the process or prevent destruction is the complete knowledge of the ingredients in the raw materials.

With these complete records at hand it is possible in most cases, if the mechanical manipulation of the process is the same day out and day in, to speedily overcome any unevenness in the working of the plant due to any increased or decreased amount of admixtures to the raw materials.

The utmost care in regard to the raw materials will undoubtedly repay in more than one way, but perhaps equally important from another point of view is the careful chemical control of the various steps in the chemical process. Day out and day in without fail the routine analyses—the safety valve of the process—have to be made and tabulated.

The tabulation of the analyses from day to day is exceedingly important. It shows at a glance how the whole process is working and whether the fullest yields at the different steps are obtained. The more graphical the tables are the more valuable they are. The day to day variations are often scarcely noticeable, but the week to week and month to month, and often year to year, variations count, and if they are carefully studied often losses can be avoided and improvements noticed that otherwise would totally have slipped attention.

This daily factory record is of fully equal importance to the operation of the factory as the log is to the captain of a vessel to bring it safely into port. The records have to be planned and kept in such a manner that they give sufficient information, making it possible for a person familiar with the work to take them up thousands of miles away and be able to draw conclusions and direct the operation of the plant at that distance. Any clerk sufficiently instructed can keep the records, but the planning and the drawing of valuable conclusions from them are only possible for the chemist with an observing mind and a wide knowledge.

Where chemical control to the full extent of the meaning of the word is instituted in the factory there is no hesitancy in mode of operation; complications that may arise can be traced to one or more factors, which will be very apparent after a comparative study of the records, and after doing this it will be in most cases an easy matter to bring back the process into the successful grooves.

The factories where chemical control is not instituted and no records exist excepting such as may by chance have been scribbled on the wall by a foreman or a laborer, or scattered notes in the office with no meaning at all, are in a state of upheaval when a snag is struck. General consternation reigns. The chemist, the foreman, the laborer, the manager all have their own opinion why this and that and another thing happened, and what is the most expeditious way of overcoming the trouble. Time is lost and the whole process is liable to be upset with subsequent money loss to the stockholders.

The "chemical balance sheet" is, again, a record which is of equal importance with the "chemical control." The former deals exclusively with weights, while the latter deals exclusively with percentages. The "chemical balance sheet" is generally understood to represent the bookkeeping of the process. The balance sheet has to be kept up for every day with the same care as the bank keeps up its balance sheet. Every cent has to be accounted for which has been handled during the day in the bank. Similarly should the factory management be able to account at the end of the day for every pound of the raw material stock, how far it has gone on its way through the factory, how great the losses are in the different steps of the process, and finally should the losses, together with the amount present in the finished product, total up to the raw material stock consumed during the day.

In some processes these items are hard to obtain daily, especially so in continuous processes. In such cases the balancing should be done at as frequent intervals as possible to avoid any cumulation of errors. This balancing of the process cannot be too rigid, missing nothing, and should in accuracy compare with the financial balancing of the assets and liabilities.

In close connection with above records come the determinations of the efficiency[2] of the various steps and apparatuses used in the process. The factory with the highest efficiency record is the most economical factory, and is the money-making factory, often much to the astonishment of its competitors. It is able to pay dividends, while its competitors are barely able to keep the wheels turning.

The daily records of the efficiency will quickly show their value and repay the trouble in keeping them. Suppose that an apparatus designed to dry with steam only utilizes 50 per cent of the drying capacity of the steam at that temperature, it is apparent that an enormous waste of fuel and calories takes place at that point. This would not be noticed to its full extent excepting by the careful keeping of a daily efficiency record.

In any chemical or electrochemical industry it is possible to determine efficiencies. They may be relative or absolute. The absolute efficiency is in some cases impossible to obtain, and while the absolute is very much desirable, the next best is a relative efficiency. The zero point from which to start the efficiency determination has to be arbitrarily chosen, and it may occasionally happen that the efficiency shows a figure higher than 100 per cent, which only indicates that the zero point has been chosen too high.

The points briefly dealt with above are very far reaching. They are not new, though altogether too little attention is given them for the good of the chemical industries and the pockets of the stockholders. The same principles have been applied to questions of money in the financial world and in other industries. In the chemical industries, perhaps due to the comparative vagueness of these, since they do not deal with measures as tangible as in other industries, these principles have been slow to be applied. But they have been applied in some chemical industries, and those are the money-making ones, prospering even though there may be very heavy competition and a very small margin of profit.

Niagara Falls, Canada.

American Vanadium Facts is the title of a new and neat house organ issued by the American Vanadium Company, of Pittsburgh, Pa., miners of vanadium ores and manufacturers of "Amervn" ferrovanadium. The first issue, which has just been received, contains articles on general properties of vanadium and ferrovanadium, on vanadium steel forgings, on vanadium steel governor pins and their endurance and on vanadium steel castings. The Union Steel Casting Company, of Pittsburgh, is reported as having obtained recently the following results with vanadium steel castings: Tensile strength, 123,090 pounds; elastic limit, 86,220 pounds; elongation in 2 inches, 10 per cent; reduction of area, 15.6 per cent. These figures were obtained on 34-inch blooming mill pinions. After a special heat treatment a coupon from these pinions gave 20 per cent elongation and 40.6 per cent reduction without material change in the tensile and elastic figures.

[2]When I speak here of efficiency, I generally mean the "scientific" efficiency, although in some cases, under practical conditions, it may be more economical to aim at what might be called the "commercial" efficiency. Undoubtedly in most cases the economical way of operating is trying to reach the upper goal which is the "scientific" efficiency. But under special conditions and in special processes, the aim at reaching a high efficiency may influence the quality of the product or the output to such an extent that it may be better to aim at an efficiency that has been established through practical working as being the most economical, and this may be called the "commercial" efficiency.

A French Plant for the Fixation of Atmospheric Nitrogen

In our February issue, pages 102 and 103, a brief description was already given of the new works of La Nitrogene Company in La Roche-de-Rame, Hautes-Alpes, France, using the Pauling process for making nitric acid and nitrates from air.

A very full description of the same plant is given by Jules Vanderpol in the January issue of *La Houille Blanche*, from which the following translation has been prepared.

Reactions.

The chemical reactions are summed up as follows: The reaction in the arc in the electric furnace is

$$N + O = NO \qquad (1)$$

The gases which leave the electric furnace have a temperature of 900° C. to 1000° C. and contain 1 per cent to 1.5 per cent NO and 98.5 per cent to 99 per cent air. When this gas mixture is cooled to 600° C. the NO reacts with the oxygen in the air according to the equation

$$NO + O = NO_2 \qquad (2)$$

This reaction is somewhat slow on account of the low concentration of NO in the gas mixture (the speed of formation being inversely proportional to the concentration of NO) and is complete only at a temperature of 130° C. It is, therefore, necessary to let the gas mixture remain for some time in the large-sized tower in which this reaction goes on. This is the object of the oxidation tower which follows the cooling apparatus.

There remains the absorption of NO_2. As a matter of fact the gas is really a mixture of NO_2, NO, N_2O_3 and N_2O_4, the N_2O_3 being formed by the reaction of NO_2 on NO and the N_2O_4 being due to the partial polymerization of NO_2 in the oxidation tower.

The gas is subjected to the action of water at a temperature near 30° C., the reaction being

$$3\,NO_2 + H_2O = 2\,HNO_3 + NO \qquad (3)$$

Secondary reactions also take place, the oxides N_2O_4 and N_2O_3 reacting with the water as follows:

$$N_2O_4 + H_2O = HNO_3 + HNO_2 \qquad (4)$$

$$N_2O_3 + H_2O = 2\,HNO_2 \qquad (5)$$

These reactions are immediately followed by the decomposition of nitrous acid.

$$3\,HNO_2 = HNO_3 + 2\,NO + H_2O \qquad (6)$$

These reactions take place in the acid absorption towers. According to (3) only two-thirds of the NO_2 is changed to nitric acid, the remaining one-third being reduced to NO.

According to (6) only one-third of the nitrous acid is oxidized to nitric acid, the remaining two-thirds being changed to NO. Hence, a new oxidation of NO becomes necessary. This is the reaction between the peroxide NO_2 and oxide NO.

$$NO + NO_2 = N_2O_3 \qquad (7)$$

The absorption by water is completed by a reaction with soda

$$N_2O_3 + H_2O = 2\,HNO_2 \qquad (8)$$

$$2\,HNO_2 + Na_2CO_3 = 2\,NaNO_2 + CO_2 + H_2O \qquad (9)$$

The nitrite produced always contains a certain proportion of nitrate, since the gases when they leave the absorption towers do not contain exactly one molecule of NO for one of NO_2. The NO predominates and the reactions are

$$3\,NO + NO_2 + 5\,O = 2\,N_2O_5 \qquad (10)$$

$$N_2O_5 + H_2O = 2\,HNO_3 \qquad (11)$$

$$2\,HNO_3 + Na_2CO_3 = 2\,NaNO_3 + CO_2 + H_2O \qquad (12)$$

These last reactions take place in the nitrite tower. These are the principal reactions. In reality they are still more complex and change with temperature, pressure, speed and quantity of gases in movement, etc.

La Nitrogene Company Works.

Electrical energy for the works at La Roche-de-Rame of La Nitrogene Company is generated from water-power, there being four turbine-driven main generators, each of 2000 hp. The energy is transmitted over an overhead transmission line of aluminium of 600 m (2000 ft.) length to the furnace house.

The furnaces are installed in a hall (Fig. 1), 15 m (50 ft.) wide and 45 m (150 ft.) long. They are built of fire brick reinforced with steel and are arranged in groups of three. Their horizontal section is 1 m x 1.20 m (3 ft. 3 in. x 3 ft. 8 in.) and their height is 3 m (10 ft.). Their design is characterized by simplicity and robustness.

The design of the furnace is shown in Fig. 2 in several sections. Each furnace contains two vertical chambers *f f*, each chamber containing a pair of electrodes *e e* of the form of a horn lightning arrester, as shown in the diagram at the right-hand bottom of Fig. 2. The electrodes are of steel, interchangeable and inside cooled by circulating water.

The arc between the two electrodes is blown upward into the form of a large sheath 60 cm to 70 cm (24 in. to 28 in.) high by means of hot compressed air, which is blown into the furnace through the tuyère *t* at a speed of 400 m per second. To permit the air to rise between the electrodes, the latter

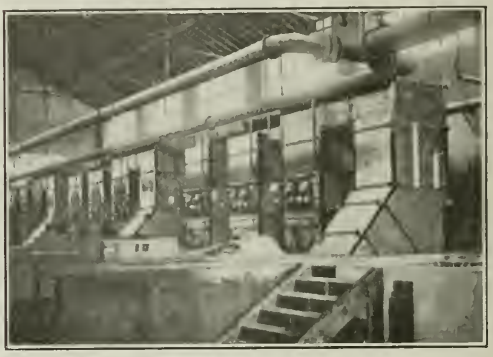


FIG. 1.—FURNACE HALL.

should not be too near together. But the distance between the two lower ends must also be sufficient to light the arc. To overcome this difficulty Pauling uses auxiliary electrodes *c* ("couteaux d'allumage") in form of thin copper blades, the ends of which can be brought near together (2 mm to 3 mm or 80 mils to 120 mils) to light the arc again if by accident it should be extinguished.

i are insulators, *f* is the passageway through which the cool air enters, *s* is the exit of the gas mixture produced. The wall which separates the two arc chambers from each other contains in its center another channel *u* by means of which a cold gas mixture is fed to the upper portion of the arc flame. This gas mixture ("umlauffluft" or circulating gas) is taken from the gases which have already been subjected to the reaction and have been cooled in their passage through the cooling apparatus. The "Umlauffluft," therefore, serves to cool the gases coming from the arc, without diluting their content of nitrogen oxides. This "Umlauffluft" is not indispensable for the satisfactory operation of the furnace, as the plant has worked satisfactorily without the "Umlauf" being in use.

The copper blades forming the auxiliary electrodes last in the average 20 hours and can be replaced in a moment. The main electrodes last 200 hours, as they are internally cooled.

An opening in the exit passage *s* of the gases permits the introduction of a pyrometer for measuring the temperature and of a pressure gage to control the fan which sucks the gases to the cooling apparatus.

Each furnace has two arcs in series. The 50-period, 6000-volt, three-phase currents supplied from the power plant are used directly. The furnaces are single-phase and the three phases of the three-phase supply are connected to the three sets of furnaces in each group, respectively.

The electrical accessories are two self-inductance coils, a transformer used in starting the arc and a rheostat, all being placed in front of each furnace.

Nine furnaces, each of 600 kw, are in normal operation, but the installation of 1000-kw furnaces is contemplated, as they are more stable in operation and have a higher efficiency.

The air supplied to the furnaces comes from a 250-hp turbo-compressor running at 3000 r.p.m. The air is preheated in a preheater built of metallic tubes, the heat in the gases coming from the furnace being used to preheat the gases which go to the tuyères.

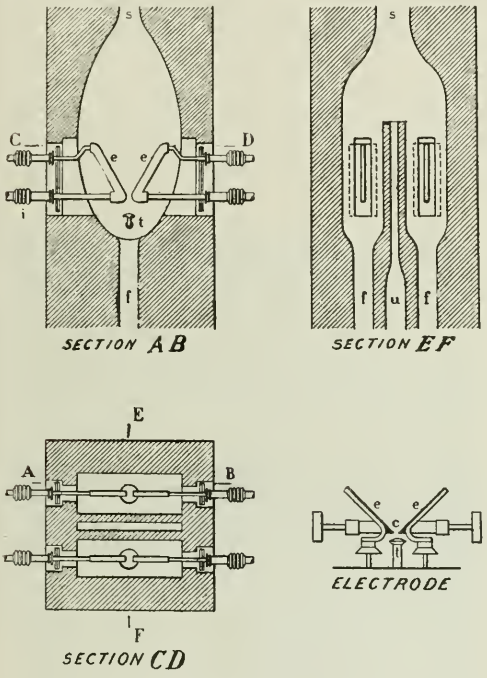

FIG. 2.—SECTION OF FURNACE.

Fig. 3 is a diagram of the electrochemical plant. *B* is the furnace house, *E* the preheater, *F* the groups of furnaces, *D* the repair shop and laboratory, *R* the cooling towers, *G* a chimney, *O* the oxidation tower, *N* nitrite towers.

H is the absorption shed containing the absorption towers A_1, A_2, A_3, A_4, A_5 and the concentration apparatus C_1 and C_2, while the acid is stored in *M*.

The gases coming from the electric furnace contain 1.15 per cent to 1.50 per cent of NO and have a temperature of 900° C. to 1000° C. They are first passed through the preheater *E*, where they give off some of their heat. This is important from the viewpoint of energy economy.

The gases are then passed through the cooling towers *R*. These two towers are alternately in operation. They are 5 m (16 ft.) in diameter and 12 m (40 ft.) high and are filled with brick which offers a large surface to cool the gases. When the bricks of one tower *R* have become hot, the gases are switched over so as to pass through the other tower, while fresh air is passed through the first tower (natural draught being obtained by means of the chimney, which is 26 m. or 85 ft., high) and the brick in it is thereby cooled. Hence while the gases are cooled and the brick heated in one tower, the brick in the other tower is cooled by fresh air, and so on.

The oxidation of NO to NO_2 begins when the temperature of the gases has sunk to 600° C. But this temperature is not yet reached in the cooling towers.

The gases are now sucked out of the cooling towers by means of a 15-hp fan which produces suction as far back as in the furnaces. By the fan the gases are driven into a large reinforced concrete tower, called the oxidation tower and shown in Fig. 4. It is 23 m (75 ft.) high, 10 m (33 ft.) in diameter and the thickness of the walls is 10 cm (4 in.).

Two lines branch off at this point. The first branch line represents the "umlauf" gas line through which part of the cooled gases is returned to the furnaces.

The second branch line consists of an aluminium pipe line, cooled with water, and this is put in service when the cooling by the towers has not been sufficient.

The oxidation tower (Fig. 4) is filled with acid-proof refractory brick. It is in this tower, in which the gases remain for a relatively long time, that the cooling of the gases is completed and the NO is changed to NO_2.

The absorption apparatus and concentration apparatus for the acid are placed in the shed *H*, in Fig. 3. This is 22 m (72 ft.) high and covers an area of 15 m x 30 m (49 ft. x 98 ft.).

The absorption of the gases by the water takes place in the five absorption towers A_1, A_2, A_3, A_4, A_5 (Fig. 3), through which the gases pass in the direction from A_1 to A_2 to A_3 to A_4 to A_5, while the water (gradually containing more and more acid) flows in the opposite direction.

Montejus, operated by compressed air, raise the solution to

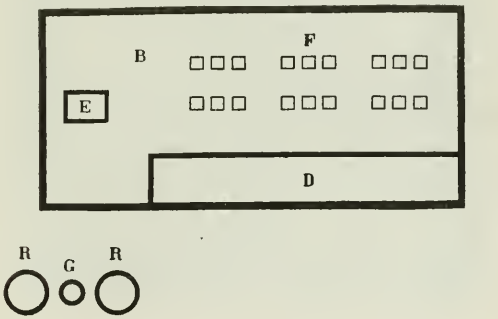

FIG. 3.—DIAGRAM OF ELECTROCHEMICAL PLANT.

the top of the different towers. Each tower contains 250 tons of acid-proof stoneware packings.

In general the concentration of the acid in the tower A_5 is 5° Beaumé, further 8° to 10° Be in A_4, 12° to 15° Be in A_3, 18° to 20° Be in A_2, and 25° to 30° Be in A_1, which corresponds to 35 per cent to 40 per cent of HNO_3.

From the absorption tower A_1 the acid is passed to the concentration apparatus C_1 and C_2 (Fig. 3). It is passed through a series of porcelain or fused-quartz vessels arranged in stairway fashion. While passing through the vessels the acid is

heated by direct contact with hot gases which come from the furnace. These gases are thus charged with water and nitric acid vapor. To condense the nitric acid the gases are passed through a cooling coil of stoneware which offers a very large cooling surface. The gases are then passed into the oxidation tower, where they mix with the gases coming from the furnaces.

The acid obtained by this concentration process contains about 50 per cent HNO_3 (about 36° Be) and it is possible to push the concentration up to 60 per cent (40° Be) by this process. But further than this it is not possible to go in this way, since the vapor produced has a concentration which increases with the concentration of the solution, and for a con-

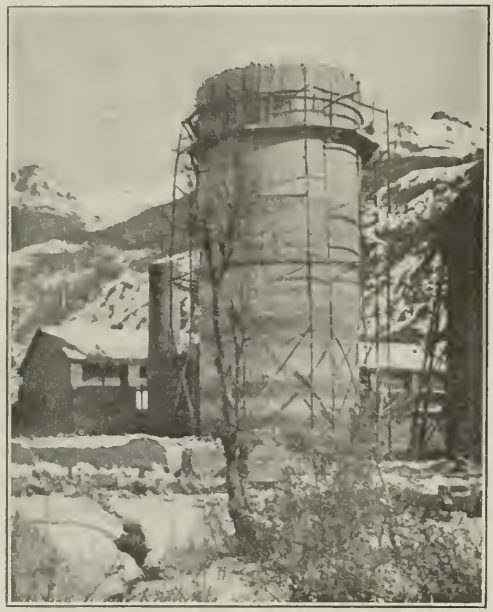

FIG. 4.—OXIDATION TOWER

centration of 60 per cent the vapor produced has exactly the composition of the liquid.

To obtain higher concentrations other means must be resorted to. At the Patsch plant an electrolytic process of Pauling is used (as described in his United States patent, noticed in our Vol. VI, 1908, page 300). But on account of the high cost of the apparatus, which requires considerable amounts of platinum, this method is not used in the French plant

In the latter the following process is employed: The nitric acid, of 60 per cent, is mixed with two parts of its weight of sulphuric acid of 92 per cent, then introduced into a tower filled with Volvic packing and heated from the outside In this way a nitric acid with a concentration of 98 per cent may be easily obtained. The sulphuric acid withdrawn from the bottom of the tower, which has been diluted by the absorbed water to a concentration of 77 per cent or 80 per cent, is concentrated and then used again.

The gases which pass out of the absorption towers contain NO and NO_2. They are passed through an acid filter in which the last traces of the acid are condensed. The gases then pass into the nitrite towers (V in Fig 3), when they are caused to react with a sodium carbonate solution. The sodium nitrate solution obtained has a concentration of 20 per cent, and is then submitted to evaporation. The hot furnace gases are used for this purpose. The nitrite crystals obtained are white and contain 95 per cent nitrite and 3 per cent nitrate.

The sodium carbonate solution used in this part of the process is the only raw material employed in the plant besides atmospheric air and water.

As to the efficiency it is stated that Pauling guarantees a yield of 60 grams of 100 per cent acid per kw-hour of electrical energy, measured at the entrance of the electric transmission line into the factory. Pauling also guarantees that the cost of the electrochemical plant proper is not more than 120 francs ($24) per kilowatt.

The Process of Zinc Distillation

By George A. Wettengel.

The experiments that have been in progress for the last year at one of the zinc smelting plants in Kansas with a rotatable zinc smelting furnace (United States patent 901,405; this journal, Vol. VI, November, 1908, page 457) will be of interest, as this type of furnace has many advantages over the present type of stationary furnace in labor saving and increased life of retorts.

The present type of furnace necessarily requires much hard manual labor and the chief object of my improvements is to provide a furnace adapted to be mechanically operated. This is accomplished in the following manner:

Fig. 1 is a front view of the furnace in operating position, Fig. 2 shows the furnace in the charging position. The furnace consists of a steel shell, with two tires supported on rollers, one of the tires has a gear attached, engaging the driving mechanism by which the furnace can be rotated to any desired position. The inside of the shell is lined with tile, with suitable shelves for suporting the retorts. The pipes supplying

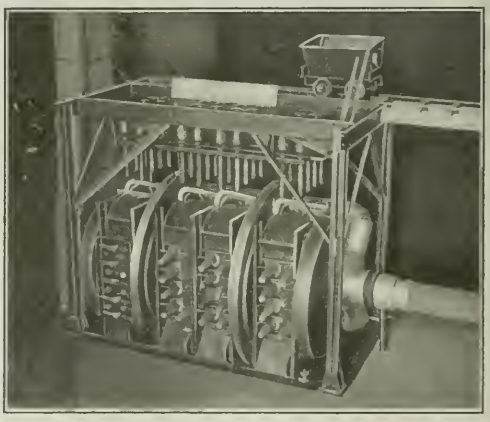

FIG. 1.—ZINC FURNACE IN OPERATING POSITION

gas and air to the burners are attached to and rotate with the furnace.

Above the furnace is the charging floor, containing hoppers, each just large enough to hold the ore mixture for one retort, with shut-off slides and telescopic spouts that are lowered to the top of the retorts so that all of the ore mixture goes into the retorts. Below the furnace is a large hopper for the residues

The ore mixture is dumped onto the charging floor, each hopper filled, and then the furnace is rotated upward so that the retorts are vertical with their open ends in line with the hopper spouts. These are now lowered and slides opened, whereupon the ore mixture falls by gravity into all of the retorts

simultaneously. Then the furnace is rotated downward so that the retorts are now in a horizontal or any position which may be desired for the destillation.

The condensers are put on, luted, stuffed and vented. After completing the distillation process the condensers are removed and the furnace again rotated so that the retorts are vertical, but have now their open ends downward. The residues then fall out by gravity into the hoper under the furnace.

The furnace is then rotated again so as to bring the retorts into a horizontal position and is then cleaned of adhering loam and any remaining residues and then recharged as before. But instead of rotating it to its first operating position it is now rotated with the open ends of the retorts pointing in the opposite direction. The retorts are now 180° from their first operating position. This inverts the retorts so that the bottom of each is used as the top, and vice versa. This brings the slags to the top of the retort chambers, which it melts and drips down onto the distilling ore mixture and is discharged with the residuum.

This inverting of the retorts makes them practically self-cleaning, almost entirely avoid scraping, and increases their life by using two sides. It keeps them practically straight.

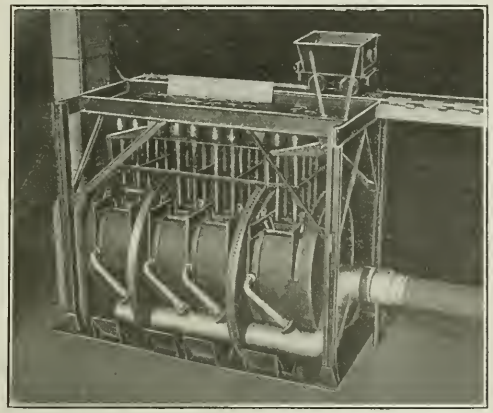

FIG. 2.—ZINC FURNACE IN CHARGING POSITION.

This method avoids the present danger of cracking the retorts and of the slags perforating them.

Distribution of Charge and Dryness of Ore Mixture.

To charge the present type of furnace the charger stands in front of the white-hot retorts facing the charging car which contains the ore mixture and shovels the contents of the latter into the mouths of the retorts, filling them one by one with a semi-cylindrical scoop, requiring eight or nine scoopfuls to fill a retort, the amount depending on the force and skill with which it is thrown in by the charger. This slow process is not only hard, laborious and unhealthful work, because of the intense heat, but also unsatisfactory as all of the retorts do not receive the same amount of ore mixture, it being packed unevenly within the retorts.

The ore is charged into the retorts wet enough to stick together, requiring about 15 lb. (2 gal.) of water per retort. This not only chills the retorts and absorbs heat to distill off the water, but also retards the process of zinc distillation. The steam generated by the intense heat frequently expels the entire charge before it can be vented (commonly called spiessed).

With my rotatable furnace each retort is charged simultaneously from individual hoppers from the charging floor above with a predetermined amount of ore mixture which is uniformly distributed throughout their length. This greatly reduces the time of charging, dispenses with the chargers, necessarily decreasing the cost of operation, increases the time for the distillation process and also increases the capacity of a furnace.

The ore mixture is charged dry, necessarily a more rapid and thorough distillation of zinc is obtained with a considerable saving in fuel consumption without the present danger of chilling the retorts or expelling the entire charge. Thus a more rapid and thorough distilling process is attained with an increased life of the retorts by dry charging.

Sagging of the Retorts.

Since the retorts in the present type of furnaces are only supported at their ends, they gradually sag and distort, not being strong enough to preserve their shape and successfully support the weight of the contained ore mixture and resist the intense heat to which they are subjected during the zinc distilling periods.

The compressive stresses produced in the upper half of a retort by the weight of the contained ore mixture is safely resisted while the bottom half is in tension, the stresses of which the material cannot safely resist as it has a very low tensile strength.

The retort continues to sag until it fails by cracking across the bottom. This not only requires replacing the retort, but occasions large losses of zinc.

With a rotatable furnace any tendency of the retorts to sag, distort, crack or lose their shape from the weight of ore mixture and the intense heat to which they are subjected during the process of zinc distillation is resisted by inverting them for each distillation process. This not only keeps them practically straight, but also avoids the present danger of losing their shape and cracking, necessarily increasing their life and the zinc recoveries.

Slags Perforating the Retorts.

In the present type of furnaces the tops and sides of the retorts are not seriously affected by the repeated distillations, the bottoms, however, are usually attacked by the corrosive slags and perforated, particularly when the ore treated contains a large percentage of iron, manganese or lime. After a retort has been perforated the slags will drip on top of the retort lying below, which will also be perforated, but from the outside. This not only occasions large losses of zinc, but necessitates replacing the retorts.

In a rotatable furnace the slags formed and adhering to the bottoms of the retorts during the process of zinc distillation are brought to the top by inverting them for the next distillation process. The bottom being on the top and vice versa. This adhering slag gradually drips off of the retort and drops on top of the smelting ore mixture and is discharged with the residuum. This not only prevents all the slags from accumulating on the bottoms of the retorts, which reduces their capacity and efficiency, but prevents the corrosive slags from perforating the retorts as in the present practice.

After rotating the furnace downward for discharging the residue it is left in this position for several minutes, during which time small pieces of slag fall out, also burning iron which can be distinguished by bright sparks similar to the sparks from a piece of iron brought to a welding heat. These sparks of burning iron continue to drop from the top of the inverted retorts after they are brought to a horizontal position. This increases the life of the retorts by removing most of the iron and slag, which corrodes the retorts.

Uniformity of Temperature.

In bringing the present type of furnace to the proper temperature for distilling the ore mixtures in the lower tiers of retorts, the upper tiers are subjected to a higher temperature than is required. This intense unequal heat has an injurious effect on the upper tiers of retorts.

In my method the rotatable furnace with its retorts is reversed each day to overcome the unequal heating of the top and bottom tiers of retorts. This reversing brings the retorts

from the top, or hottest, to the bottom, or coolest, part of the furnace each day, thereby prolonging their life.

Condenser Loam.

In the present type of furnace the conical condensers are inserted with their large ends projecting into the open ends of the retorts about 1 in. and lying on the bottom of the latter, thus forming a crescent-shaped joint with an opening at the top of about 1 in., which must be luted up air-tight with loam. After the condensers are removed the loam adhering mostly to the upper half of the retorts must be removed each day to again admit the condensers. This is accomplished with a heavy

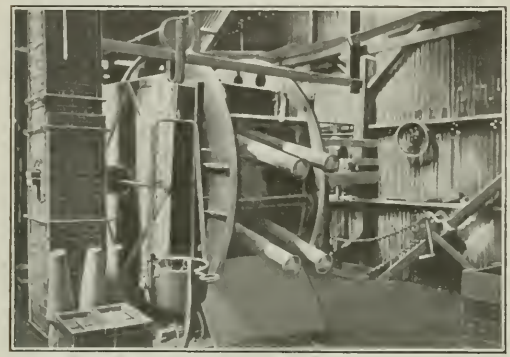

FIG. 3.—EXPERIMENTAL FURNACE IN OPERATING POSITION.

bar, commonly called a bumper, with which the workman bumps off the adhearing loam frequently, chipping off small pieces of the retort with it, until they become leaky or breaking them so that they must be replaced. In a rotatable furnace the retorts are inverted each day, bringing the loam on the top one day and on the bottom the next and vice versa. This greatly reduces the present danger of chipping or breaking the retorts in removing the loam.

Metal Drawing.

In the present type of furnace the metal is drawn off by inserting an iron scraper into the ends of the condensers and scraping out the loam stuffing and the liquid metal into a ladle attached to a crane conveniently supported on a truck which travels on a track parallel with the working face of the furnace. When the ladle is full of metal it is swung out from the furnace, the top skimmed off and its contents poured into molds. Occasionally a condenser is knocked loose accidentally whereby the liquid metal rushes out covering the metal drawer, often seriously burning him. This is very hard, dangerous and unhealthful labor on account of the intense heat and fumes escaping from the ends of the condensers.

In my method the metal is drawn off by rotating the furnace to an angle of about 15 deg. below the distillation position, whereupon the metal rushes out of all of the condensers simultaneously into a trough extending the length of the working face of the furnace and then collects in a ladle at the end. The contents of the latter is then poured into molds. This not only requires a fraction of time to draw the metal as compared with the present method, but greatly reduces the hard, dangerous and unhealthful labor, as the operator is away from the intense heat, fumes and liquid metal issuing from the condensers.

Agitating the Ore Mixture

I rotate my furnace upward after each drawing of metal so that the ore mixture falls by gravity to the rear ends of the retorts. I then continue rotating the furnace until the retorts are again brought to the distillation position, but inverted. By this occasional agitation of the ore mixture the particles of ore and carbon will be more thoroughly mixed and brought into more intimate contact with new surfaces whereby a more rapid and thorough distillation process is attained. This not only increases the recoveries of zinc, but also reduces the time required for the process of zinc distillation.

Composition of Residue.

In the present type of furnace the ore mixture is not uniformly distilled, necessarily the residues at the open ends of the retorts are rich in zinc because the ore mixture does not receive heat enough to thoroughly distill it. Two in. or 3 in. of this residue (called sampling) is scraped out of the open ends of the retorts and is mixed with the ore mixture to be charged for the next distillation process. This not only increased the labor, but reduces the amount of fresh ore mixture that can be charged into the retorts.

By rotating my furnace after each drawing of metal so that the retorts are brought with their open ends upward the ore mixture falls by gravity to the rear ends of the retorts, thereby bringing the ore mixture from the open ends of the retorts where it receives insufficient heat to the rear ends where it will be thoroughly distilled. This not only greatly reduces the labor and increases the amount of fresh ore mixture that can be charged into the retorts, but increases the recoveries of zinc.

New Retorts.

In the present practice when a new retort is placed in a furnace it is not charged the first day, this time being allowed for burning and glazing the retort. A retort is replaced 12 times a year, necessarily losing 12 days per year by not being charged. In a rotatable furnace the retorts are replaced 2 4/10 times a year, necessarily losing only 2 4/10 days per year for burning and glazing. An increase of 9 6/10 days per year per retort capacity of a furnace, or an increase of 9 7/10 per cent in capacity. This greatly increases the capacity of a furnace without any additional labor.

Heat Transmitting Efficiency.

In the present type of furnace with its stationary retorts the heat transmitting efficiency decreases as the slags accumu-

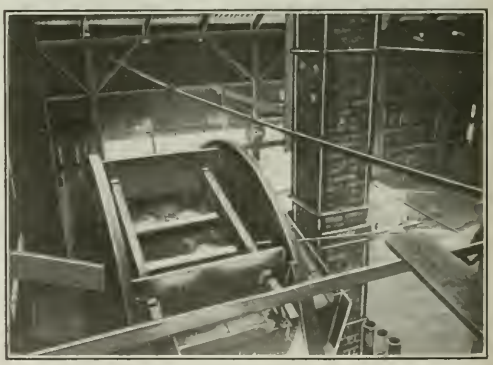

FIG. 4.—CHARGING POSITION OF EXPERIMENTAL FURNACE

late on the bottom of the retort chamber until it is from 3 in. to 4 in. thick during its 30 days' use, necessarily considerable more fuel is required to bring it to the proper temperature for the distillation process than for a new retort.

In a rotatable furnace with its inverting and self-cleaning retorts the slags formed on the bottom of the retort chamber during the distillation process one day are brought to the top of the retort chamber by inverting them for the next distillation process, whereupon the slags drip off onto the smelting ore mixture and are discharged with the residues. These slags corrode the walls of the retort, decreasing their thickness and

necessarily greatly increasing their heat transmitting efficiency.

Capacity of a Retort.

In the present type of furnace with its stationary retorts the slags gradually accumulate on the bottom of the retort chamber until it is from 3 in. to 4 in. in thickness, necessarily greatly reducing its capacity.

In my rotatable furnace with its inverting and self-cleaning retorts the capacity does not decrease, but remains the same until replaced.

In my rotatable furnace the ore mixture is charged dry. It is possible to charge about 10 per cent more ore mixture dry than wet as it fills the retorts more compactly.

Temperature of Furnace While Charging.

In the present type of furnace the heat is practically shut

FIG. 5.—RETORTS.

off for several hours during the charging operation, necessarily greatly reducing the temperature of the furnace at a period when it is necessary to bring the cold and wet ore mixture in the retort to the distillation temperature as quickly as possible.

In my rotatable furnace the temperature is not reduced except as required during the distillation process. All the retorts are charged simultaneously from individual charging hoppers from above with dry ore mixture, therefore, greatly reducing the cooling off period while charging.

Use of Metal Tools.

In my rotatable furnace there are no metal tools used in drawing the metal except the last drawing. This not only prevents breakage and abrasion of the condenser, but greatly reduces the absorption of iron from the metal tools used and a purer metal is obtained.

Fig. 3 is a front view of the experimental rotatable furnace in the operating position. The furnace is rotated as required by means of a wrench and link belting which engages sprocket wheels on the shafts of two of the supporting rollers. It has six ordinary retorts 8 in. in diameter by 48 in. long inside dimensions. To maintain the temperature as nearly uniform as possible pyrometric cones were used inside of one of the retorts (No. 2) as an aid in regulating and recording the temperature. Therefore, only five of the retorts were charged. The furnace was charged in the usual way for several months with such excellent results that I decided to try charging it from the top to demonstrate its practicability.

An inclined runway and platform was constructed to charge from. The platform was on a level with the working face of the furnace when in the charging position. After the residues were discharged, the furnace was rotated so that the retorts were in a vertical position with their open ends upward (see Fig. 4).

It was now charged from above by wheeling the ore mixture up the incline runway onto the platform, then shoveling it into the vertical retorts, filling them one by one with dry ore mixture instead of wetting it as in the present practice. After all of the ore mixture was charged, the last retort was only about one-third full, thereby demonstrating that considerable more dry mixture could be charged into the retorts than of the wet.

The furnace is now rotated to the operating position and the distillation process continued similar to the best present-day practice. The top charging was discontinued after charging about one week as it was hard work to wheel the ore up the steep incline runway.

Fig. 5 shows the six retorts after they were removed from the furnace, having been in 167 days. These retorts are practically as straight as on the day they were put into the furnace. Compare these with the crooked retort to the right of No. 6, which was taken from one of the ordinary type of furnaces after being in use less than one month.

Retort No. 1 was cracked accidentally in putting it in the furnace. It was charged 81 times. Charging was then discontinued as the crack was opening up and losing zinc.

No. 2 was never charged. Pyrometric cones were put in this retort to regulate the temperature.

No. 3 was charged 151 times when a small hole was discovered in one side.

No. 4 was charged 167 times and was still in excellent condition.

No. 5 was charged 143 times when a small hole was found in one side.

No. 6 was still in excellent condition after being charged 167 times.

Fig. 6 is a view of retort No. 4 cut in two, vertically, showing it to be in excellent condition after being in continuous operation for 167 days. There was very little slag in it, and very little corrosion had taken place as the walls of the retort were from ¾ in. to ⅞ in. in thickness. None of the retorts were perforated by the slag.

This is a remarkable showing when compared with the life

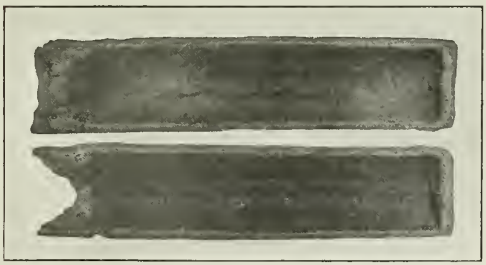

FIG. 6.—RETORT NO. 4 CUT OPEN.

of retorts in the usual type of furnace, which average about 30 days.

Joplin ore was used in these experiments with 4 per cent to 5 per cent iron.

The average loss was 8 per cent. This is an excellent showing considering the small size of the furnace and the difficulty in maintaining the correct temperature.

After the retorts were removed from the furnace a new set was put in, which were in continuous operation for 154 days. The retorts were still in good condition at this time.

St. Louis, Mo.

Pure radium has been prepared by Madame Curie, who announced her success in September, 1910. The production of radium salts has not increased greatly, and the cost of obtaining them, either by purchase or loan, is still excessively high. Prices are quoted at about $100 per milligram. Radium is loaned in Paris for scientific purposes at a cost of $100 to $200 per day for 100 milligrams. The production in France in 1910 was 1.92 grams, and was sold for about $150,000.

Recent Progress in Calorimetry.

The Real vs. the Supposed Errors.

By Walter P. White.

In pure science and in its technical applications an important place belongs to calorimetry, the measurement of quantities of heat, of heat energy, of heat as distinguished from temperature. It is well known that nearly all large users of coal or other fuel no longer buy by weight alone, but by fuel value, thus actually paying for heat, the thing they are really after. The fuel testing made necessary by this practice is probably the most extensive and familiar use of the calorimeter, but nearly every physical or chemical process is accompanied by a heat effect whose determination is necessary for complete knowledge, and heats of fusion and vaporization, variations of specific heat with temperature and pressure, and heat effects accompanying solution, dilution and other chemical processes occupy prominent places in the literature of their respective subjects.

In spite of its importance, calorimetry has been singularly backward in development and has long been considered to be a subject wherein high accuracy was probably unattainable. Within the last five years, however, a great improvement has taken place. A careful study of the various sources of error—which in itself furnishes a good example of the value of systematic scientific methods—has shown that previous practice was largely based on notions and estimates widely at variance with fact and has rendered possible a progress based on knowledge. In considerable part, however, it is only fair to say the improvement has been due merely to the application of a little common sense to practices which rested on nothing but the thoughtless acceptance of traditions handed down from earlier and cruder days. The net result is that the measurement of heat in a calorimeter may now usually be made more accurate than the necessary associated determinations. For instance: Weighing is well recognized as one of the most accurate of physical determinations. In determining the heat of combustion of many substances the error may now be no greater than the unavoidable error in weighing the sample.

The calorimetric method in which this progress has been most conspicuous is the most common and familiar one, often known as the method of mixtures; it alone will be regarded in the present paper.

In principle the mixtures method is exceedingly simple. Heat is added to a vessel of water (or other fluid) and the resulting temperature rise is measured. The heat is then given as simply the product of temperature rise by the heat capacity of the water and calorimeter. The numerous complications occurring in practice all arise from one cause—the loss of heat which begins as soon as the water is heated. This (1) necessitates a correction, the "cooling correction," for the heat lost; (2) requires experimental arrangements which increase the difficulty of dealing with evaporation; (3) calls for stirring, and the stirring, if effective, produces appreciable heating; (4) makes it necessary to take observations of time, since the temperatures are continually changing; (5) gives opportunity for error if in the various changes any parts of the system fail to follow the change quickly enough; opportunity, that is, for "lag" errors of various sorts.

Of these complications the cooling correction has generally been counted the chief. Omitting details for the present, the principle of the cooling correction is as follows: The heat loss can be found if we know two things—the temperature of the calorimeter, and the way in which the heat loss depends on that temperature, or the "cooling constant," as it is called. Observations on the calorimeter temperature are easily made during the heat transfer. Observations of the cooling rate, made before and after the transfer period, define very accurately the "cooling constant" for the particular set up and the particular half-hour of the experiment. A simple calculation then gives the correction.

This procedure, in the form just outlined, evidently assumes that the environing temperature remains constant, since this also affects the cooling of the calorimeter. To promote this constancy the calorimeter has usually been surrounded by a water jacket, except at the top, which is left exposed to the air of the room. This arrangement is evidently far from perfect, for the jacket temperature also may vary, and the influence of the room is not wholly excluded. And, in fact, the changes may easily be of sufficient amount to be a source of error. The remedy, however, is easy and simple; it is to make the jacket surround the calorimeter completely and then measure the temperature of the jacket and allow for any changes. This gives directly the difference of calorimeter and jacket, which is really the quantity on which the heat loss directly depends. This method is one of the recent improvements and has been adopted independently by several different workers. If certain slight lag effects are also guarded against, the cooling then depends on simple, definite conditions which are thoroughly known. Since the whole correction is only a few per cent of the total heat quantity measured, there would seem to be no reason why it should cause appreciable error.

There has been, nevertheless, a widespread opinion that the cooling correction error is the largest in calorimetry, and that this condition is almost unavoidable. Indeed, this belief has probably gone far to discourage attempts at reducing the other errors. No adequate experimental evidence appears ever to have been offered in favor of this notion as to the hopelessness of the cooling correction, and lately decisive evidence has been obtained of its falsity. For instance: In a recent series of over 100 calorimetric determinations at the Geophysical Laboratory the time, the initial temperature, etc., were varied among the various observations so as to make the relative magnitude of the cooling correction vary within wide limits. Although the average accidental error was only from 20 to 40 parts per 1,000,000, and most of that was evidently due to the temperature measurement, yet there was no sign of any error due to the cooling correction. With proper precautions, therefore, the cooling correction error is not only not large, it is imperceptible. The hopelessly uncertain cooling correction is a myth.

With *evaporation* the case is altogether different, and irregular evaporation is probably responsible for much of the irregularity attributed to the cooling correction. There are cases where, in work intended to be specially accurate, the published data show that the heat loss by evaporation was often quite as great as that due to the regular cooling. Evaporation depends on a condition, the saturation of the air, which is at once very variable and hard to determine. Hence, as a rule, the only satisfactory way to regulate evaporation is to prevent it. Fortunately, this is not difficult.

Two ways are available. One, of course, is simply to cover the calorimeter tightly. The other is to cover it loosely, or not at all, but to keep it below the temperature of the jacket. In that case the air within the calorimeter chamber very soon becomes saturated at the temperature of the coolest body in it, the calorimeter, and evaporation then ceases. Of course, there will be a little more evaporation when the calorimeter is warmed, but the total amount of this can be kept small by restricting the size of the calorimeter chamber. For instance, if a 2-liter calorimeter is heated 2 deg. and the air space around it is only 1 liter, the heat abstracted by the extra evaporation will not be far from three calories, or about 0.8 per mille of the total heat measured. If a correction is applied for this, the *error*—that is, the uncertainty—will be only a few tenths per mille. Of course, this assumes that the chamber is well inclosed all the time, that its walls are thoroughly dry, and that care has been taken to keep well above the dew point. The evaporation of small drops of water from the *outside* of the calorimeter is especially productive of error on account of its great uncertainty. The remedy is obvious.

The *heat produced by stirring* is much less serious than the effect of evaporation, but may still cause appreciable error if improperly treated. This is because the heat production in-

creases at least as fast as the third power of the speed of stirring, so that a stirring rate only a little in excess of what is necessary may cause a rather large surplus of heat. Previous practice has almost universally been widely astray in this matter. For instance, Richards and Burgess have shown that stirring has nearly always been insufficient. The opinion has also been common that reciprocating stirrers, with horizontal vanes moved up and down, give less heat for equal efficiency than screw propellers. The opposite is the case. The greatest objection to the reciprocating stirrer, however, is the increased evaporation it usually causes.

The object of stirring, of course, is to secure inside the calorimeter uniformity of temperature; just how great this uniformity must be will depend on the accuracy sought. The heat of stirring will not be a source of error so long as it is constant, for it can then be allowed for, but its variations, due to variation in the speed of stirring, will cause error, and a variation of 1 per cent in the rate will cause a variation of 3 per cent in the heat. Of course, by regulating the speed closely enough it will nearly always be possible to avoid appreciable heating error, but what is wanted practically is to secure uniformity of temperature without making careful regulation necessary. The ideal calorimeter would be accompanied by a statement of the proper speed of stirring for any given error due to uneven temperature, and of the heat production at that speed. The allowable variation in speed could then be found at once. As it is, the user will generally have to determine these quantities for himself.

(1) The greatest error from lack of uniformity in temperature is usually due to the lag of the surface of the calorimeter behind the center while heat is being added; this is easily determined if a thermo-element can be used. (2) The heat of stirring can easily be found by observing for alternate periods of 10 minutes (say) with the stirrer first in action, then still, etc., and the calorimeter very near the temperature of the jacket.

In one calorimeter (with propeller) of 1½ liter capacity, stirring, certainly effective enough to reduce the error from uneven temperature below 0.025 per mille, raised the temperature about 0.001° per minute. This would demand a speed of stirring constant to 6 per cent for an accuracy of 1 per mille with a 2° rise and 10-minute interval. This result may be useful as a rough guide for those who are not in a position to make thermoelectric observations, but who can, of course, determine the heat of stirring.

In this case the error from heating would ordinarily greatly exceed that from uneven temperature, hence slower stirring would usually be better. With stirring one-third as fast the error from uneven temperature would still probably not exceed 0.08 per mille (for the same time and temperature intervals), and the error from heating would be no larger than this, even with a speed varying 10 per cent. On the other hand, if the speed were to be doubled, the heating would be 0.1° in 10 minutes, and the accuracy would be very limited, even with a stirring speed regulated to 1 per cent. This shows very clearly the disadvantage of a speed even a little too great. It should be added that the *error* from uneven temperature here is (arbitrarily) taken as one-sixth the actual temperature difference. The calorimeter here referred to was especially designed for facility in stirring; there were no dead spaces where the water could linger, and the flow of the circulating water was not throttled at any point.

The timing of the observations should never cause appreciable error. For, let K be the cooling factor of the calorimeter—that is, let the calorimeter cool in one minute the fraction K parts of its excess temperature above the jacket. K, for ordinary calorimeters, is not very far from 0.003. Hence a calorimeter, starting at jacket temperature and heated by any amount, will cool about 1/330 of that in each minute, or 50 1,000,000 of it in one second. As the timing can easily be done to half a second, the probable error will be less than 25 parts per 1,000,000. (If the calorimeter does not start from the jacket temperature the error will not be very different.)

The relation between time error and proportional temperature error thus depends on the cooling rate of the calorimeter. This relation is important, for it also holds for all lags.

The *lag effects* are rather complicated, but fortunately the only serious ones are easily preventable.

The one most prominently advertised thus far is the thermometer lag. A mercury thermometer will often lag ten seconds or more behind the fluid surrounding it, thus making its readings higher than the real temperature of a cooling calorimeter. Ten seconds, we have just seen, corresponds to a temperature error of 0.5 per mille. The thermometer lag, however, has lately been shown to involve no error, because it enters both in the cooling correction determination and in the final temperature, and enters oppositely in the two, so that *if the same thermometer is used throughout* the two opposite effects are equal and cancel each other. The simplest way to demonstrate this is to consider that a uniform lag on *all* the readings amounts to the same thing as reading them correctly, but a few seconds earlier each time—which, of course, would introduce no error. (For a more complete demonstration those interested may be referred to several articles on calorimetry in the *Physical Review* for November and December, 1910. These articles also supplement the present paper in other respects.)

The unavoidable lag effects are (1) the lag of the cooling itself: as the calorimeter is heated it takes a little time (about two seconds) for the air currents to get started around it. (2) The very trifling lag of the projecting metal parts of the calorimeter. (3) The lag of the surface behind the center as the calorimeter is heated. This is due to the time required for the heat to pass outward through the water, and depends on the rate of stirring. It may be, under proper conditions, from three to nine seconds. The total effect of these unavoidable lags, therefore, may be from five to eleven seconds, or from 0.25 to 0.5 part per mille. But these lags also have this property: their effect is independent of the manner of heating, whether sudden or slow, but is always proportional to the temperature rise. Their effect, therefore, is precisely equivalent to that of a slight change in the heat capacity of the calorimeter. Hence, if a calorimeter has been calibrated, and is not afterward changed, the error due to these lags will be altogether inappreciable, otherwise results will (as far as their influence is concerned) be consistent, but subject to a systematic error about equal to the present uncertainty in the specific heat of water.

Two remaining effects are perhaps better regarded not as lags, but rather as cases of variable environing temperature. These are the effects of non-metallic supports or projections, and of covers not touching the calorimetric fluid. Such bodies warm up gradually after the calorimeter is heated, and during all that time the heat flow into them is changing in an unknown way. For instance, calorimeters have been known to be set on a solid plate of hard rubber, a gratuitous introduction of error so needless as to be quite inexcusable. A safe rule is to make all non-metallic supports so small that their total heat capacity is negligible, which is easily done. The stem of a glass thermometer, however, may introduce a slight error through its varying temperature. Uncertainty in the temperature of the cover can be avoided by depressing the center of the cover so that a considerable part of it touches the water.

The determinations at the Geophysical Laboratory, mentioned above, were, of course, subject to error from evaporation, stirring and lag. Hence those results show that accidental errors from *all* these causes taken together may be made quite inappreciable.

The chief *unavoidable calorimetric error*, then, is just where it would be if a perfect heat insulator existed—that is, in the temperature measurement.

The rise of temperature employed in calorimeters is seldom over 4 deg., and often less than 2 deg. The most sensitive mer-

cury thermometers are rarely read closer than to 0.001 deg. Now, even with perfect judgment on the observer's part, and perfect behavior of the instrument, there is evidently always a possible accidental error of half the smallest unit recorded. But two to four accurate thermometric readings enter into a single determination. Hence, the unavoidable accidental thermometric error may be as high as 1 per mille, altogether aside from imperfections in the instrument or the observations, which will ordinarily make the error still larger.

Two remedies are possible. The first is to increase the *precision* of the thermometric measurements. This has hitherto called for electric thermometers. These, of course, are complicated in comparison with mercury thermometers, though they also have some decided advantages besides the increased precision. There is, however, a second and very easy method of reducing the thermometric error, and that is to increase the temperature interval by diminishing the amount of water heated or by increasing the amount of heat. This method runs contrary to a generally accepted opinion which insists that small temperature intervals are necessary for accuracy. But the reasoning on which this opinion is based appears upon examination to be rather unsatisfactory. That reasoning, briefly, is as follows: The heat loss from a calorimeter is not proportional to the excess of temperature above the environment, but increases more rapidly than it. If heat loss is plotted against temperature difference the result is a line which curves upward. Now this curve, like all curves, can be made to differ as little as we please from a straight line by dealing with a sufficiently short portion of it. And so, by limiting sufficiently the temperature rise in the calorimeter, it is possible to use a linear cooling law—that is, to take the cooling as proportional to temperature difference, which, of course, simplifies calculations somewhat. Hence a small enough interval should be used to make the cooling law linear—say, from 2° to 4°.

It is evident that this reasoning does not indicate that actual error will arise from the use of a large interval unless the observer insists on coupling with it a computation based on the linear law appropriate to a small interval. But he is not in the least obliged to do this, and there is no question that the proper expression will represent a large interval quite as well as the approximate linear law does a small one, thought not quite so simply. Hence the only considerable advantage of the short interval is a saving in labor, and while this may sometimes be worth while it is, of course, a trifling consideration whenever accuracy is of importance. Moreover, the extra labor involved in cooling computations for large intervals may, by a method to be described later, be made to average less than a minute per determination, and the error from improperly assuming a linear relation for an interval of 8° is no greater than that of the best calorimetric determinations yet made with mercury thermometers. Hence the generally accepted view that small intervals are conducive to accuracy and generally advantageous is a fallacy. (The small interval may, however, be advantageous in cases where the thermometric accuracy is more than sufficient for the object in hand.)

With a mercury thermometer the gain in accuracy from using a large interval would probably not be proportional to the increase of the interval. Just how great the gain would be in any given case is perhaps a little uncertain at present. With electrical thermometers the gain at first is practically proportional to the increase in interval and even for a 10° interval and with the best instruments the error in the thermometer is probably considerably larger than that in the calorimeter itself.

The increase of the interval meets with an obstacle in the important department of combustion calorimetry, for the water must circulate freely about the bomb and hence its amount often cannot be readily reduced. But it does not seem impossible to get around this difficulty in a satisfactory way. To take one possible method out of several: If the bomb itself were used as the stirrer, being raised and lowered by a wire, the stirring of even a small amount of water would be more effective than that of a larger amount by the customary reciprocating stirrer, while the great drawback of the reciprocating stirrer, evaporation, could in this case be easily controlled.

The foregoing article has pointed out that the cooling correction, instead of being the largest, is easily made the least of the sources of calorimetric error, that evaporation, while much more serious, can also be controlled without difficulty, as can the heat produced by the stirrer. The way to control evaporation is to practically prevent it. With the stirrer the essential thing is to find the proper speed. Lag effects, though numerous and complicated, may easily be made to produce negligible errors. The total inaccuracy of the calorimeter, therefore, is much less than the usual error of the temperature measurement. This error can be greatly reduced, though at the cost of considerable complications, by using electrical thermometers. It can be very easily, though less effectively, reduced by increasing the temperature interval through which the calorimeter is heated. The general opinion that small intervals are generally advantageous or conducive to accuracy is a fallacy.

In a subsequent article there will be considered the practical application of these conclusions to the various details of a calorimetric determination.

A Commercial Nitrogen Plant.

By Albert Alexander Somerville.

The air we breathe is a mixture of nitrogen and oxygen. The latter is a supporter of respiration. It is also a supporter of combustion. Nitrogen is just the opposite. It will not support combustion nor is it itself combustible under ordinary conditions. When studying the properties of a substance at elevated temperatures it is desirable to prevent that substance from combining with oxygen to form an oxide. This can most readily be done by working the substance in a vacuum or an atmosphere of nitrogen or hydrogen in order to exclude the oxygen.

Obtaining a vacuum at room temperature, and keeping it while the temperature is being raised in a furnace, are two things of different degrees of difficulty. A containing vessel through which gases will not pass at high temperatures when the pressures inside and outside are different is a rare thing. Someone has said that a vacuum is the cheapest thing you can produce, but it requires a lot of trouble to retain it.

If a metal is to be annealed it must be heated to a considerable temperature. A partial vacuum may be obtained and so only a small amount of oxygen allowed to unite with the metal to form an oxide. If it is desired to completely prevent oxidation then it is better to fill the containing vessel with some other gas so that the pressure inside and out will be equal and, therefore, reduce the tendency for the oxygen or the air to enter. Or, still better, if the inside pressure can be maintained at a value slightly higher than that of an atmosphere, thus causing a slow leakage outward, the chance for oxygen to enter is very small.

Two gases that may be used for filling the vessel are hydrogen and nitrogen.

Hydrogen is readily obtained by the decomposition of water, H_2O, by an electrical battery into hydrogen and oxygen, collecting the two gases at the two poles of the battery. Due to the low specific gravity of hydrogen a tube may be kept filled with it to the exclusion of other gases simply by inverting the tube and admitting the hydrogen at the lower open end. The two objections to its use are that hydrogen passes through the walls of a heated vessel about the easiest of any gas, and also that in some proportions with air it forms a dangerous explosive mixture.

On the other hand, nitrogen is readily obtainable from the air, of which it forms about 78 per cent by volume. It is

neither combustible under ordinary conditions of practice, such as are here considered, nor a supporter of combustion, nor does it enter readily into combustion with any other element. Also it does not so readily pass through the walls of a containing vessel.

Nitrogen is obtained by separating it from the oxygen of the air. This is done by causing the oxygen to unite with something to form an oxide and so leave nothing that will support combustion or oxidation. It may be noted that the air consists of about 99 per cent nitrogen and oxygen and the remaining 1 per cent consists of a group of gases known as the

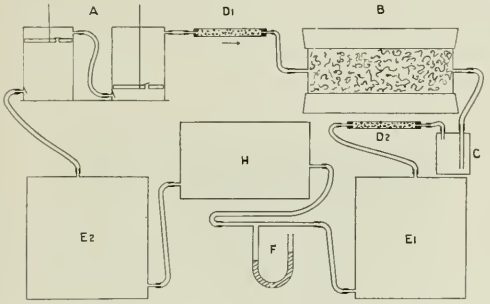

FIG. 1.—DIAGRAM OF APPARATUS FOR SEPARATING NITROGEN FROM AIR.

argon groups, none of which support combustion, and also one other, namely, carbon dioxide.

The oxygen of the air may readily be made to unite with burning phosphorus and so leave nitrogen, or air may be passed over hot copper with which the oxygen unites to form copper-oxide and thus leaves only nitrogen in which any other metal may be heated without oxidizing. The equation representing the chemical change is simply

$$Cu + O = CuO.$$

A nitrogen producing plant may be made on this principle that is quite efficient. The highest efficiency is reached by having a cyclic process and using over and over again the same product. The same is true of any kind of a system, for instance, in a refrigeration plant the same ammonia is used over and over again.

In a nitrogen plant a cyclic system may also be used consisting of a motor-driven pump, a furnace containing metallic copper, storage tanks, drying agents, pressure indicators, meters to measure rate of flow, and lastly the station at which it is desired to use the nitrogen, all connected in series so that the same gas is continually flowing through the same circuit. Such a system probably has the highest efficiency possible.

The diagram, Fig. 1, shows the general scheme. A is a pump (two cylinders in series), B a furnace containing copper, electrically heated, C a wash bottle, indicating flow of gas, D_1 and D_2 dryers, E_1 and E_2 storage tanks, F a pressure gage filled with mercury, and H the station where the nitrogen is used. The capacity of the storage tanks and conduits is nearly a fixed quantity and may be made anything desired.

The pump may be any of several motor-driven types for the movement of gas, and the rate of flow of the gas may be regulated either by varying the speed of the motor and pump or, what is better, by running these at normal speed and adjusting the partially closed stopcocks.

If there is an oil immersion used in the pump A it is well to follow this by a drying tube D, in order to remove any moisture from the air before it enters the furnace. This may consist simply of a large glass tube filled with calcium chloride or phosphorus pentoxide.

From this drying tube the air passes into the furnace and over the heated copper. Here the copper is oxidized and the oxygen of the air unites with it to form copper oxide. The gas that remains is principally nitrogen and will not support combustion or oxidation. The furnace is made by filling an iron pipe 3 in. in diameter and 2 ft. in length with copper shavings or droppings, capping the ends of this pipe, tapping small pipes into these caps for an inlet and outlet and providing an electrical heating coil around this receptacle.

This electrical heater may be made of wire or ribbon wrapped around the iron pipe and insulated from it either by a roll of asbestos paper or by special kinds of fireclay. The wire may be covered on the outside with asbestos or mineral wool for thermal insulation. This furnace is run at a temperature somewhat above visible red heat, 600° C. to 800° C., and if the air is not passed through it too rapidly practically all the oxygen is removed on the first trip around the circuit.

In order to determine the rate at which the gas is flowing a meter may be put in circuit, or if only a general indication is desired a wash bottle C may be used to indicate, by its bubbling, the general rate of flow and in this wash bottle something may be used, such as pyrogallic acid and potassium hydroxide, to remove any remaining traces of oxygen that may have passed through the furnace.

This wash bottle may be followed by another dryer D_2 in order to catch any liquid or vapor that may be carried over from the bottle and then connect with a storage tank E_1 and pressure gauge F. The storage tank may vary from the size of a bottle to that of a gasometer as desired. Since the pressure is generally only slightly above an atmosphere an ordinary mercury manometer may be used to indicate pressure and will indicate any large leaks.

The gas is now available for use and may be run into any station or place where it is desired. Presumably this would be a second furnace where it is desired to heat some substance in which oxidation is to be prevented. In the case of the writer he has used it in connection with the measurement of the electrical resistance of about 40 materials up to temperatures approximately 1000° C.

The nitrogen is not allowed to escape the air from this furnace, but instead is carried to another storage tank and eventually back to the pump at the starting point. Since the plant was filled with pure air at the start and about 20 per cent by volume has been removed to form copper oxide, the pressure would accordingly fall making a tendency for air to leak in from the outside in order to equalize the pressures. This may be remedied by providing an intake right at the pump so that any new air that comes into the circuit must at once pass over the heated copper and so have its oxygen removed. Finally

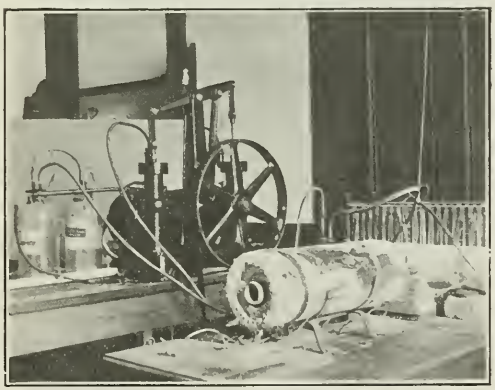

FIG. 2.—VIEW OF APPARATUS.

the circuit becomes thus practically filled with pure nitrogen.

All connections are made with pressure tubing with joints well covered with shellac.

Due to keeping the inside pressure of the circuit above one atmosphere there are usually some small leaks so that a fresh supply of air must be pumped in occasionally. In order to remove the oxygen from this copper must be changed into copper oxide and so the supply of metallic copper is finally depleted.

In order to convert the copper oxide back to metallic copper it is only necessary to disconnect the furnace from the remainder of the circuit and run illuminating gas through the furnace while it is hot. The hydrogen in the gas unites with the oxygen of the copper oxide to form water and leaves metallic copper and carbon dioxide. The equation representing it is as follows:

$$4\,CuO + CH_4 = 4\,Cu + 2\,H_2O + CO_2.$$

This reduction is easily accomplished and the furnace is then connected into the nitrogen circuit again.

Cornell University.

Evaporators and Vacuum Pans.

By B. Viola, M.E.,

Member American Society of Mechanical Engineers.

Evaporation for the purpose of concentrating liquid plays a most important part in the sugar and the chemical industries. This process is accomplished in any of three different ways: viz., by heating the liquid by the combustion of fuel, by heating the liquid with indirect steam heat, and lastly, by indirect steam, with simultaneous reduction of atmospheric pressure upon the surface of the heated liquid, lowering the boiling point.

Any liquid exposed to the atmosphere will evaporate more or less rapidly at ordinary temperature. The normal pressure of the atmosphere at sea level is equal to that exercised by a column of mercury 29.92 in. equal to a pressure of 14.707 lb.

FIG. 1.—SUGAR MANUFACTURE IN SICILY IN 1570. (FROM THE "NOVA REPERTA" COLLECTION OF JOANN STRADANUS.)

per square inch. At this pressure water boils at a temperature of 212° Fahr. If the pressure be decreased the boiling point of water or any liquid falls and it is due to this phenomenon that multiple-effect evaporating apparatus can be constructed in which 1 lb. of steam may evaporate in practice up to 5 lb. or 6 lb. of water. The evaporation increases with rising temperature; it increases until evaporation takes place not only on the surface, but all through the bulk of the liquid when the boiling point is reached. The temperature of such exposed liquid cannot increase while the liquid is boiling, as any addition of heat will but accelerate the process of evaporation.

The heat of evaporation can be determined for any liquid. The total heat of steam is $t + t_1$, where t is the amount of heat in heat units, or thermal units, which must be communicated to the liquid in order to accomplish the boiling of it. t_1 is the amount of heat which evaporates the boiling liquid.

The heat required to raise the temperature of 1 lb. of water 1° Fahr. is called the British thermal unit and to convert 1 lb. of water at 212° Fahr. into steam at 212° requires 966 b.t.u. This item is called heat of evaporation. The quicker this heat is added to the boiling liquid the quicker the evaporation will take place.

Different liquids have different boiling points and are also influenced by the presence of bodies in solution.

The amount of water evaporated in a unit of time is in direct proportion to the heating surface with equal temperature.

Increase of temperature of the heating medium has the same effect as increase of heating surface—that is, the amount of water evaporated in the time unit is directly proportional to the temperature of the heating surface, its dimensions remaining

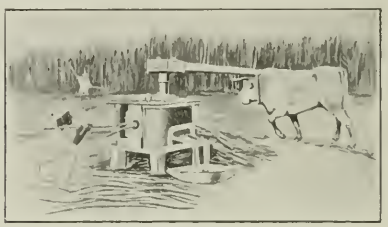

FIG. 2.—EARLY METHOD OF EVAPORATION.

equal. It is by far easier to enlarge the heating surface, hence this is always attempted in the construction of plants.

The earliest systems of evaporation were those on open fires in flat or cylindrical shaped open pans (Figs. 1 and 2). These systems can still be found for boiling sugar juices in India and in the West Indies, especially where families boil their own sugar from the juice of sugarcane. We find the first improvements in evaporators at the beginning of the nineteenth century when Dubrunfaut constructed his rocking-pan. This has a flat bottom which is heated by coal or wood fire and has a bill-shaped mouth for emptying the same. In Fig. 3 *A* is the pan, *a* the mouth, *b* an axle placed in the bearings, *c* is a moving and *d* a fixed roller for raising the pan. *B* is the oven, *G* the fire grates and *b* the fire door.

Halette's construction (Figs. 4 and 5) was a considerable improvement in evaporators. In this, *A* is a copper tank with a half-round front piece *B* with valve *a* in the bottom. This evaporator rests by two buttons on two iron plates *b* which are fastened on the wooden support *c*. At *e* is an iron leg which is turning around the axle *f* like a leg of a table. By loosening the bolt *d* the bolt plates could be turned aside and the tank could be lowered by turning the leg *e* around the axle. On the rod *g* hangs the rost-shaped heating apparatus, consisting of two prisms *hh* with 24 cone-shaped holes in them where the 24 copper tubes are tightened by bolts *i*. The steam enters through the pipes *ll* and from there passes in the direction of the arrows to the copper heating tubes, holes being drilled in the prisms *hh* between the pipes for that purpose. The use of this apparatus was not very advantageous, as the steam entering the heating pipes condensed too quickly and the pipes filled with water, which was difficult to drive off because of the high pressure required, which often burst the pipes.

Neither the evaporating system on open fires nor those with steam pipes, placed in the bottom of open kettles, could give satisfactory results, especially in the manufacture of sugar. First, the evaporation was too slow; a great amount of sugar was destroyed on account of the high boiling point and then the heating capacity of the fuel and steam was very poor. Therefore, some better method was necessary to increase the evaporative capacities of the kettles.

In order to consider everything connected with the building of such evaporators we can say that:

a. Besides the heating surface, the heat-conducting power of the material, of which the heating surface is composed, is very essential. According to Wiedemann and Franz, in Poggendorf's *Annalen*, the relative conductivity of silver is 1000; gold, 532; copper, 736; iron, 119, and lead, 85. Silver would, therefore, furnish the most efficient heating surface, but its high price excludes it from practical use for this purpose. We generally find copper employed for sugar, malt, tannin, etc., while lead or lead-lined copper and iron are used for the evaporation of acids. Further,

b. The thickness of the heating surface decreases the conductivity of heat transmission. However, the thickness employed for copper in practice is sensibly constant.

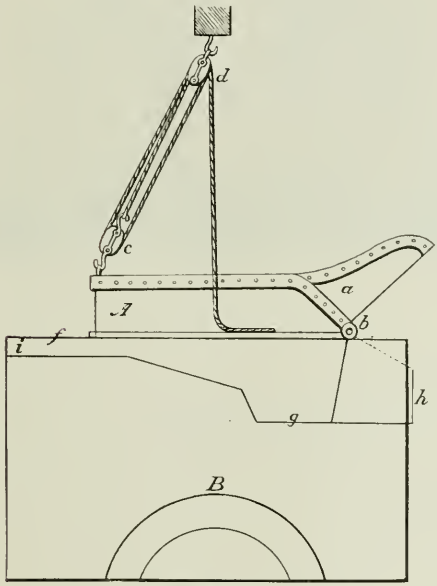

FIG. 3.—DUBRUNFAT ROCKING PAN

c. The transmission of heat is directly proportioned to the mean difference of temperature.

d. Thick or viscid liquids acquire heat more slowly than water or thin liquors and in such cases the coefficient of transmission is often only 0.5 or 0.2 of the coefficient of water.

e. The transference of heat is reduced to an undeterminable degree by incrustations with crystals or scales.

f. When a continuous change exists in the flow the quicker liquids or steam are dirven through the heating pipes the quicker will be the heat transmission. The shorter and smaller the diameter of the steam-heating pipe the more efficient is the heat transmission.

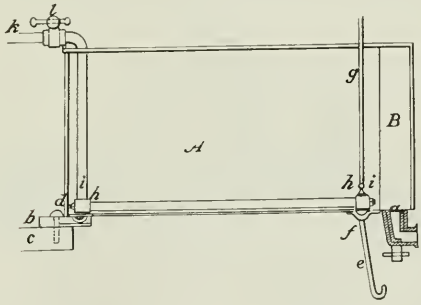
g. The transmission of heat is affected also by the position of the heating tubes.

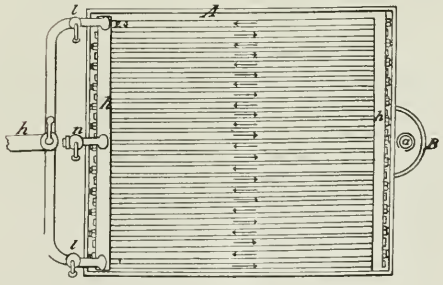
With vertical tubes the condensed water is always running down on the whole surface and prevents the conductivity of heat because the steam is not in intimate touch with the heating surface; while with horizontal tubes the condensed water drops off quickly and the steam can effect its full heating capacity. Boiling depends not only on the material and area of the heating surface, but also on the pressure resting upon the surface of the liquid which is to be evaporated. The lower the pressure the less resistance the steam bubbles find in rising to the surface and so, of course, boiling can be reached by a lower temperature. This is always the case with evaporators and vacuum pans, where the boiling of the liquids is done under a partial vacuum.

The vacuum in an evaporator is always given in inches of mercury. Thus a vacuum of 25 in. means that the excess of atmospheric pressure over the pressure in the effect would support a column of mercury 25 in. high; hence, expressed as a pressure, a vacuum of 25 in. means a pressure of 29.92 — 25 in. = 4.92 in. = 2.42 lb. per square inch.

The first apparatus for a reduced pressure was built in 1813 by Howard (Fig. 6) and is shown in section according to J. Foster. *A* is a boiler for boiling the liquid. It is formed of two copper pans strongly bolted together and has a double bottom where the vapor is supplied by the pipe *C; D*, the condensed water pipe to which is attached the air cock; *E*, dome in which the vapors are collected and the syrup which may be mechanically drawn in with the vapor falls again into the vessel; *G*, the condensing vessel to which a pipe is attached and communicates with the air pump; this pump maintains the vacuum, but is not shown in the plan.

The cold water enters the space *C* through the opening *H* and by moving the handle *I*, the valve *K* and the piston *L* are raised. *F*, the vapor pipe from the pan to the condenser. This is used for returning the liquid drawn in by the vapors into the space *O*, from where it is easily removed by the cock *R; M* is the cold-water feed pipe; *N*, a proof-stick for taking a proof of the syrup in the vessel without opening communication between the interior and the air outside; *Q*, thermometer which indicates the temperature of the syrup.





FIGS. 4 AND 5.—HALETTE EVAPORATOR

This apparatus spread among the English colonies and on account of its advantages it was possible to get 1/6 larger results than with the open pans. The temperature difference between condensed water and syrup was 9° to 12° and the interior pressure about 50/76 and 55/76 atmosphere. For the condensing of 500 kg of vapor 10 cu. m to 11 cu. m of injection water was used and reached a temperature of 30° C.

This had several disadvantages, however; it was not possible to watch the boiling, because the vessel was closed; the dis-

charge of the syrup was very slow and needed too much power and steam. In later years the evaporating effect was improved by placing a serpentine inside and also glasses for seeing inside the vessel.

After Howard's apparatus was built Roth constructed one in France which had a jacket also and a serpentine inside (Fig. 7). The steam became condensed by a heavy water injection. The condensed water receiver had to be large enough to hold the whole quantity of one charge and was discharged after each operation. A vacuum was made before the operation started through a stream of steam (Fig. 7).

The boiling vessel *A* is similar to Howard's, but it contains a serpentine in which the steam circulates. *D* is a vessel made of iron for condensing the vapor. It is fitted with a vacuum gage *m* and a water gage *n*. *E*, the steam pipe communicating with the boiler; *F*, *G*, *H*, cocks for admitting the steam to the double bottom, the serpentine and the vessel. F_1 and G_1, cocks for the condensed water flowing from the double bottom and the serpentine; *i*, butter cock to prevent the mass from becoming frothy; *K*, syrup supply cock and pipe; *L*, outlet cock for the boiled syrup which is discharged into the vessel *O*; *M*, the vapor pipe to the condenser; *N*, metallic perforated plates, through which the cold water runs in very small streamlets and through which the vapor passes; *P*, injection cock connected to the pipe *S* which supplies the cold water; *Q*, cold-water supply cistern; *R*, cock for discharging the hot water and the air at the end of each stroke.

It is operated as follows: The vesel being empty the cocks

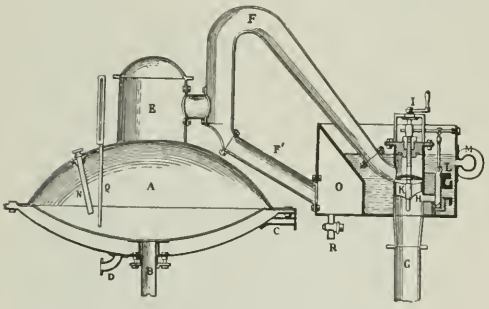


FIG. 6.—HOWARD EVAPORATOR

H and *R* are opened and the steam rushed into the vessel and into the condenser. A mixture of air and steam escapes by the cock *R* and after a few minutes, when it is suposed that all the air has been driven out, these cocks are shut and the cock *K* is opened to admit the syrup.

At first the liquid rises slowly with the progressive condensation of the vapor in the vessel caused by the cooling of the outer case. Afterward, when a portion of the syrup has been supplied into the vessel, it rises very quickly on account of the rapid condensation which its entrance causes.

When the syrup in the cistern is drawn out to a certain level the cock *K* is shut and *F* and *G* opened to admit the steam into the double bottom and the serpentine. The condensed water cocks are also opened and in a few moments the injection cock *P*. In a short time a proof is taken of the syrup and when it has arrived at the required point the injection cock is closed; the syrup is hot and when it reaches 80° or 90° the cock *L* is opened, also the air cock and the boiled syrup runs out. In order to begin a new operation, the cock *R* has to be opened to allow the hot water to run out and steam is again admitted to the vessel to drive out the air.

The water consumption of Howard's and Roth's apparatus should be alike and otherwise Roth's has the same disadvantages as Howard's. The vacuum could never be kept up equally, as the cooling water brought in too much air and some gases were also always discharged from the syrup mass.

For the evaporation of larger quantities of syrup Pelletan has built an improved apparatus. In Figs. 8, 9 and 10 *AA* is a half-cylindrical kettle 20 ft. long and 2 ft. in diameter and is placed in the jacket *BB*; it is covered with the top *CC* and rests on legs *VV*; *D*, a condenser, 15 in. in diameter and 6 ft. high with a valve and the record plate *I*, for regulating the cooling water, which condenses half of the steam coming from the kettle; *K*, another valve for the discharge of condensed water or to connect it with a pump; *H*, the steam inlet valve for a

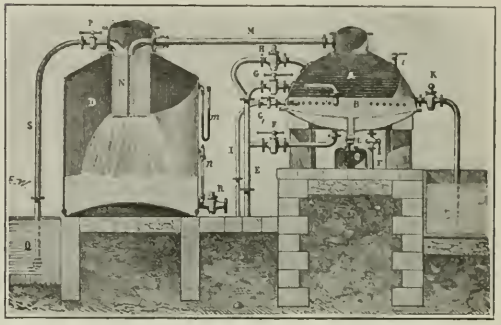

FIG. 7.—ROTH EVAPORATOR

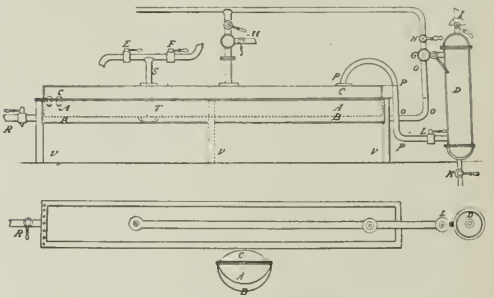
three atmosphere steam pressure in the globe *G* and from there through pipes *OO* in the jacket for the heating of the kettle.

The steam by passing the condenser *D* sucks the air out and drives it into the jacket and passes through valve *R* when the liquor reaches the cooking point. All the steam passes through pipe *PP* in the condenser and the part not condensed is carried along by the steam stream into the jacket. In this way the vapors of the kettle and the live steam together make the evaporating heat. By this method Pelleton was able to keep up a vacuum of 20 in.

Valve *L* cuts off the evaporator from the condenser and is closed when the kettle has to be discharged. With the steam valve *M* the evaporated liquid is pressed through pipe *S*, which



FIGS. 8, 9, 10.—PELLETON EVAPORATOR

reaches down to the bottom. The same pipe can be used to fill the kettle. Valve *E* is for the charging and valve *F* for the discharging of the kettle. The liquor was boiled here by 65° C. and the heating steam was 100° C. The quantity of cooling water used was about five times that of the evaporated liquid. This was the first apparatus where juice steam was used for helping in the evaporation and was first practically utilized in the United States by Rillieux in his construction, as we will see later on.

Before going further I wish to mention the capacities of the heating surfaces of the different evaporators or effects. I do

not want to figure the wearysome formula in this direction, but mention briefly according to practical experience the heating effect of a vacuum apparatus per square foot and per hour of a vacuum at 25½ in.

With exhaust steam at 230° Fahr. (20 lb.) from water, 2.5—2.66 gal.

With exhaust steam at 230° Fahr. (20 lb.), thin liquids, 1.5—1.65 gal.

With exhaust steam at 230° Fahr. (20 lb.), thick liquids, 0.73—1 gal.

With high-pressure steam, 266° Fahr (40 lb.), from water, 2.8—3 gal.

With high-pressure steam, 266° Fahr. (40 lb.), thin liquids, 2—2.5 gal.

With high-pressure steam, 266° Fahr. (40 lb.), thick liquids, 1—1.3 gal.

As stated above, if the normal pressure of 14.707 lb. per square inch can be decreased, the boiling point of water or any liquid can be lowered and this is the principle on which multiple evaporating apparatus is constructed. If steam at 212° Fahr. is condensed to water at 180° Fahr. it gives a certain quantity of heat and this is the difference between the total heat of steam at 212° Fahr.

This heat can raise the temperature to evaporate water which is boiling at 180° Fahr. under a certain pressure; the steam given up at this temperature can be used again to boil more water under a lower pressure and this way can be repeated many times.

The following system of construction can be mentioned:

a. Evaporators with horizontal heating pipes.

b. Evaporators with vertical heating pipes.

c. Film evaporators.

In constructing evaporating apparatus (and especially those with horizontal and vertical heating tubes or vacuum pans with heating coils) attention should be paid to the following points:

a. The heating surface should be as large as possible, since the larger the heating surface the quicker evaporation takes place.

b. The space above the liquid should be as large as possible in order to avoid drops of juice being carried along by the steam from the boiling liquid.

c. The pipes connecting the steam room of one apparatus with the heating room of the next should be made as wide as possible in order to diminish the velocity of the flowing steam and thus afford such particles of juice as may be carried along an oportunity to settle.

d. A juice catcher should be inserted between the evaporator and the condenser for the purpose of catching the drops of juice that may be carried along by the steam and conducting them back into the evaporator. The more the velocity of the steam is diminished in this intermediate chamber the smaller will be the loss from evaporation of the liquor.

After many trials in calculating the capacity of the actual evaporation in each apparatus of a double, triple and quadruple effect, for evaporation of 90 per cent and 75 per cent of the original weight of liquid, it was shown that the total evaporation in each vessel is constant and of the same order (Hausbrand).

The quantity of water to be evaporated in the first vessel is on an average of the total evaporation:

Double effect	0.466
Triple effect	0.300
Quadruple effect	0.216

The extreme cases:

Double effect	0.434 — 0.484
Triple effect	0.2777 — 0.3152
Multiple effect	0.1926 — 0.2335

The evaporation effected by heating is in all cases the least in the first body, but the increase in the following vessels is not very great, at most 4 per cent. In the mean it may be assumed that this evaporation in the separate vessels is in the

Double effect	1 ÷ 1.045
Triple effect	1 ÷ 1.01 ÷ 1.04
Quadruple effect	1 ÷ 1.005 ÷ 1.012 ÷ 1.02

The total quantity evaporated in the last vessel is

Double effect	0.534
Triple effect	0.3703
Quadruple effect	0.284

of the total evaporation of the apparatus.

In the mean the evaporative capacity in each vessel is in

Double effect	1 ÷ 1.045
Triple effect	1 ÷ 1.0075 ÷ 1.138
Quadruple effect	1 ÷ 1.0055 ÷ 1.109 ÷ 1.196

According to the observations made by Classen in sugar factories and similar establishments the following ratios of transmission coefficients were calculated:

Double effect	1 ÷ 0.66
Triple effect	1 ÷ 0.70 ÷ 0.33
Quadruple effect	1 ÷ 0.91 ÷ 0.75 ÷ 0.55

Should these figures be reliable and the same temperature difference taken in all the vessels the heating surfaces will be in the ratio:

$$\text{In the double effect...} 1 : \frac{1.045}{0.66} = 1 : 1.58$$

$$\text{In the triple effect....} 1 : \frac{1.0075}{0.70} : \frac{1.138}{0.33} = 1 : 1.44 : 3.414$$

$$\text{In the quadruple effect.} 1 : \frac{1.0055}{0.91} : \frac{1.109}{0.75} : \frac{1.196}{0.55} = 1 : 1.105 : 1.48 : 2.175$$

(*To be continued.*)

Notes on the Chemistry and Metallurgy of Vanadium.—II.

By Warren F. Bleecker.

Methods of Analysis.

Regardless of the fact that the analysis of vanadium ore and products may be, and in most instances is, a simple procedure, chemists do not agree as to what methods give the best results. For this reason there have been proposed a comparatively large number of analytical schemes, each of which perhaps may give concordant results if used with the care and skill presupposed by the author, but which, when used by analysts who have devoted but little time to the study of vanadium compounds, are absolutely useless so far as correct results are concerned.

Vanadium may be determined either gravimetrically or volumetrically, either directly or indirectly, and it may be reported as the pentoxide or as the metal itself. At present there is a confusion due to chemists reporting vanadium in certain compounds, especially in ores, as the pentoxide, and in other cases, especially ferrovanadium, as the metal. Because ferrovanadium is at present the most important vanadium compound and because the vanadium is in this case metallic, I prefer to follow those who invariably report vanadium as metallic and not as the pentoxide.

In general, the analyst will meet with the following vanadium ores and products for analysis: Vanadiferous sandstone, roscoelite, vanadinite, patronite and carnotite; vanadate of iron, ferrovanadium, vanadic acid. In the mill there will also be the various solutions and intermediate products which are peculiar to the methods of treatment.

It is important to remember that the various ores and vanadium products met with may require diverse procedure in order to obtain satisfactory results in a reasonable time. For example, it is very necessary to know the exact grade of a carload of vanadium ore within close limits; a tenth of 1 per cent may mean 10 per cent of the entire metallic content, a variation which (in the assay) multiplied by five in the assay of zinc ore, for example, is allowable, but which in low-grade vanadium ores should in all cases be the maximum. As a mat-

ter of fact I have always repeated assays which do not check within four-one-hundredths. On the other hand, in the assay of mill solutions and products a variation of 1 per cent or more may be allowable, excepting, of course, the final assay of marketable products.

A method of analysis should, therefore, be chosen which will give sufficiently accurate results in the quickest possible time.

For convenience of illustration and reference I have designed the accompanying analytical scheme by means of which the various methods may be compared. While there is no pretension of completeness, the outline is sufficiently comprehensive to embrace most of the important analytical methods which have been proposed.

Decomposition and Solution.

The first operation in the analysis of vanadium compounds is obviously solution, but the difficulties attendant upon the quantitative solution of vanadium are not always understood or appreciated, possibly for the reason that a portion of the vanadium content goes into solution with extreme ease and rapidity.

As will be seen by referring to the table, the following reagents are used in dissolving vanadium, no one reagent being suitable for all of the vanadium compounds met with: Sodium peroxide, caustic alkali, sodium and potassium carbonates, mineral acids and water. In some cases heat is not necessary, but in all cases heat aids solution of vanadium salts, and when the fixed alkalis are used in the dry way, fusion must be made.

It is desirable at all times to have the substance to be analyzed in a fine state of subdivision, at least through an ordinary 100-mesh screen, and in the case of ores, particularly roscoelite, to pass all of the material through a 200-mesh screen. In this way the protective surface of insoluble compounds, while relatively much greater, is thin enough to allow the dissolving reagent to act upon practically all of the vanadium in the largest of the particles present in the mass. If fusion methods are used fine grinding is not so important, yet a much lower heat is required to effect decomposition if the material is in a finely divided condition than if merely ground to 20-mesh, as is directed by the authors of some methods. And, in any event, there is nothing to be lost in fine grinding, excepting, perhaps, a little time, which is amply regained in subsequent operations and which is again paid for by confidence in the completeness of the decomposition.

There is no ore or compound of vanadium that is not attacked by sodium peroxide in a state of fusion. Decomposition by means of this powerful reagent is, therefore, the most important, and if subsequent operations of the analysis will permit a general rule might be laid down that it should always be chosen when there is any doubt regarding the reagent to be used.

Fusion with sodium peroxide may be made in either iron or nickel, the iron being attacked more vigorously, but being at the same time much cheaper. Fused silica has been tried, but with little success. In the first place it is attacked to a considerable extent by the sodium peroxide, and, in the second place, the crucibles crack after a few melts. I tried four fused-silica crucibles and obtained the same results with each. Fused silica would be desirable for the reason that the large mass of iron or nickel hydroxide would be avoided, and filtering would be easier, and the analyst could be more certain that all of the vanadium was in the filtrate upon the removal of the residue insoluble in the sodium peroxide.

Having fused the vanadium compound with sodium peroxide (melting is not necessary, and should be avoided) it is a troublesome operation to filter the alkaline solutions after the requisite amount of water has been added to dissolve the melt and dilute the alkali so that it will not attack the filter. Analysts have sought to avoid this operation by devising methods which would permit of the determination of the vanadium in the presence of iron and other substances which may be present in the original compound.

Decomposition by Sodium Peroxide.

To effect decomposition by means of sodium peroxide I prefer to mix 200 mg to 2 gm of the finely divided substance with 1 gm to 5 gm of sodium peroxide in a small nickel crucible and heat gently until the mass darkens, as may be seen after heating for a few moments. As soon as the heating is finished the mass is removed by carefully dropping the hot crucible in a small beaker of cold water, the operation being conducted as follows: About 40 cc of cold water are poured into a beaker with a capacity of at least 200 cc. The hot crucible is grasped by the edge with a pair of curved crucible tongs and dipped into the water with a swirling motion in order to avoid breaking the beaker. None of the water should be allowed to splash into the crucible at this point because of the possible loss of vanadium by spattering. The crucible is finally set in the water which will have cooled it and distributed the energy somewhat. A cover glass is placed over the beaker, and by a gentle rotary motion small portions of the water are thrown into the crucible, causing a more or less violent action and tending to throw a portion of the melt out of the crucible and the beaker as well. If care is used nothing will be lost, and finally the beaker and contents may be set on the hot plate to complete the disintegration and solution. The crucible may then be removed with a glass stirring rod, thoroughly scrubbed with a policeman and rinsed with a stream from a wash bottle. The entire operation from the time weighing was begun ought not require more than 10 or 12 minutes. The residue will settle readily in the hot alkaline solution, which may be decanted through a filter. The first wash water also may be decanted. One or two washings on the filter will remove all of the vanadium from the residue and unless washing has been carried too far, there will be no iron in the filtrate.

In case it is desired to dissolve the iron with acid it is, of course, not necessary to filter at this point, and the acid may be added directly to the solution after the crucible has been removed. In case uranium is present a considerable quantity of hydrogen peroxide is added to the alkaline solution, when the uranium will go into solution along with the vanadium. If the hydrogen peroxide is expelled by boiling before the filtration is made the uranium will be found for the most part in the residue, because the uranate of sodium is only soluble in an alkaline solution containing an excess of hydrogen peroxide.

Assuming the absence of uranium and the removal of the iron at the first opportunity, the vanadium in the filtrate may be determined in a number of ways, as will be seen by referring to the table. The very shortest method from this point on, and one which will give perfectly reliable results, is one which I devised by the use of electrolysis.

Reduction by Electrolysis.

The filtrate, free from iron and containing no uranium, is made acid with sulphuric acid and about 10 cu. cm added in excess. It is then heated to boiling and about 50 mg of pure copper sulphate added. The hot solution is electrolyzed for 10 minutes, the same procedure and current conditions being observed as in the electrolytic determination of copper with a rotating anode. The copper will not be completely deposited in 10 minutes, but it will not interfere in the subsequent titration with potassium permanganate. The solution is immediately titrated without further heating. After titration the solution is again heated to boiling and again reduced as before. The copper deposited on the cathode may be dissolved almost instantly in the solution by momentarily reversing the current, thus avoiding the use of a greater quantity than originally added. The analysis may be thus repeated as many as five times, and the results should agree as closely as the analyst can read the burette. A complete analysis may be made by this method in less than an hour, titrating three times.

Other Methods of Reduction.

The reduction of vanadium assays by means of hydrogen sulphide involves the removal of the precipitated sulphur which always separates out of the acidulated solution, and it is only necessary when some interfering second group element is present. The result must be checked by a second reduction with sulphur dioxide and it is seldom that the results agree within the allowable limit of error.

The reduction of vanadium assays by means of sulphur dioxide is the one generally employed. The results are invariably high and due correction must be made by a blank test using pure water acidulated with sulphuric acid. Moreover, the presence of sodium and ammonium salts, as well as silicates, interferes seriously with accurate work when this reducing agent is used. It is customary, therefore, to remove these substances before reduction by the lead acetate method of Roscoe, the steps of which are shown in the table. The objections to this method are the length of time involved in making the separation (especially if much silica is present) and the constant opportunity for error due to the several different manipulations involved.

Numerous methods of reduction with metallic zinc, magnesium, aluminium and the like have been repeatedly tried and without success. It is stated that one metal will carry the reduction completely to one stage of oxidation and another metal will carry it completely to another, thus providing a method of assay not involving the removal of iron, but I have never been able to do these things, and have no hesitancy in saying that so far as useful results are concerned they are impossible under the stated conditions.

A method of analysis which does not involve the separation of iron has been proposed, and is being used, I understand, by some large producers and buyers of vanadium ores and products. I have never had the opportunity of making a personal investigation of the method, but it has been highly recommended from reliable sources.

Decomposition may be made by either acids or alkalis, preferably with sodium peroxide. The crucible is removed as described above, and dilute sulphuric acid is added in slight excess. The hydrogen peroxide is destroyed by the addition of potassium permanganate, and the vanadium is reduced by the addition of ferrous sulphate, the final titration being made with potassium permanganate. The ferrous sulphate solution need not be standard and the amount added is not measured. The theory of the operation is that, beginning with a solution containing both iron and vanadium in their highest state of oxidation, the addition of ferrous sulphate will reduce only the vanadium, and the amount necessary to complete this reduction will, of course, be oxidized, and any excess of this quantity will be observed by a spot plate test, using potassium ferricyanide as an indicator.

The method in detail as follows was outlined to me by Mr Arnold J. Guerber, who, however, does not claim the invention.

Fuse 0.2 gm to 5 gm of the product or ore, depending upon the grade, with 2 gm to 10 gm of sodium peroxide in an iron crucible. Leach melt with water, heat, and add 20 cc sulphuric acid (1-1). Boil the solution until the hydrogen peroxide is decomposed, as shown by the disappearance of the red or pink color. Add sufficient permanganate to give a permanent pink. Now add ferrous sulphate until a spot test with potassium ferricyanide gives a distinct blue. Run back carefully with permanganate until this color just disappears in spot after 15 seconds. Then read $KMnO_4$ burette and titrate to a distinct pink color, which should endure at least 30 seconds. Solutions:

Potassium ferricyanide—dissolve 50 mgm in 10 cc water.

Ferrous sulphate—3 gm $FeSO_4$ and 10 cc H_2SO_4 in 150 cc water.

Potassium permanganate—1 cc = about 0.005 gm Fe.

Fe factor $\times$ 1.6316 = V_2O_5; or Fe factor $\times$ 0.916 = V.

Theoretically the method is open to objection because the action of iron and vanadium in the presence of a reducing agent is reversible, as may be easily proved experimentally.[3] If a solution of hypovanadic acid or its salts be added to a solution containing ferric iron, the presence of ferrous iron is immediately observable. According to this we should expect low results, owing to the mass action of the reduced vanadium upon the ferric iron, giving a test for ferrous iron before the vanadium is all reduced. That correct results are obtained may be due to the fact that a stated length of time is given for the spot-plate reaction to take place, or to some other modifying condition which compensates for the reduction of the iron which must take place.

A method has been proposed by means of which the titration of vanadium in the presence of iron is made directly with a standard solution of ferrous sulphate. Since the method seemed attractive a great many experiments were performed to try it out. The results were very unsatisfactory, because in almost every instance a spot-plate test for ferrous sulphate would show its presence long before reduction was complete, and there appeared to be no constant error that could be taken into account.

Separation of Vanadium and Iron.

It is usually a very difficult matter to make a complete separation of iron and vanadium. This is true on account of other elements being present, for the separation of iron and vanadium in a high-grade vanadate of iron is very easy. It is in the low iron products that the separation becomes a serious matter. The elements which interfere with the separation and which are almost invariably present are alumina and lime. In the high-grade vanadium compounds these elements are not usually present in such quantities as to affect the separation of the iron unless the product is a vanadate of aluminium or a vanadate of lime. But in the case of ores, such as vanadiferous sandstone or roscoelite, the alumina and lime are high, while the iron is low, and it is here that the difficulty arises.

If to a concentrated solution of aluminium vanadate in a mineral acid either ammonia or ammonium carbonate be added there will result a flocculent yellowish precipitate which consists of aluminium hydroxide contaminated with aluminium vanadate. If the solution be largely diluted before the ammonium salt is added the precipitate will usually be white and consist only of the aluminium hydroxide. If the above experiment be repeated, using the vanadate of calcium instead of the vanadate of aluminium, the results will be very similar. It must be remembered, therefore, that when either lime or alumina are present in the sample taken for assay the solutions must be dilute in order to effect the separation of the vanadium from these elements; indeed, all of the vanadium may be carried down under certain conditions of concentration. It is equally true that iron may also carry vanadium down as vanadate of iron, but if the solution is sufficiently dilute and there is an excess of the vanadium solvent present it is not likely that iron alone will cause the trouble that either of the above-mentioned elements will.

Care must be taken, however, to oxidize both the iron and the vanadium before attempting a precipitation. The iron must be oxidized because ferrous hydroxide, as is well known, is colloidal. The vanadium must be oxidized because salts of hypovanadic acid are partially insoluble in dilute alkalies, especially ammonia.

It will be clear, then, why sodium peroxide is the ideal reagent for separating vanadium from iron, the solutions being made dilute before attempting to filter. All of the elements are oxidized, and the aluminium goes into solution with the vanadium, as well as most of the lime. If desired, the aluminium, lime and silica may be separated later by any one of a number of methods.

If an acid decomposition has been made and it is desired to make the iron separation, we are usually advised to add am-

monia and ammonium carbonate. We are also further warned, and very properly, that the separation is not complete with one precipitation, but that several subsequent precipitations may be necessary in order to remove all of the iron from the vanadium and all of the vanadium from the iron. I have found that the separation appeared in many assays to be impossible, and after a half dozen times of redissolving and reprecipitating there was apparently as much vanadium in the iron residue as after the first precipitation. In such cases if the third precipitation be made with sodium carbonate, the separation will be complete. I have assumed that this phenomenon is due to the fact that the aluminium which was retaining the vanadium each time is dissolved, or, rather, not precipitated, and cannot further interfere with the complete removal of the vanadium from the iron.

The vanadium in mill solutions which do not contain iron may be readily determined as follows: 25 cc of the solution is diluted with about 150 cc water and an excess of sulphuric acid is added; 50 mg of copper sulphate is added to the solution and the assay heated to boiling and electrolyzed as described above. The relatively large quantities of sodium, lime and other salts present do not interfere with the determination.

Vanadic acid may be decomposed readily by digesting the assay in a hot solution of either sodium or potassium hydroxide to which a little hydrogen peroxide has been added, and the subsequent determination made by any method desired. If one attempts to decompose vanadic acid which has been fused, with an acid, the operation will be found to be tedious and unsatisfactory, whereas the alkali will effect a complete solution almost immediately if there is an oxidizing agent present.

Inaccuracies of Some Methods.

There are a number of methods which are not included in the table, because of their inaccuracy or general unfitness for commercial work. Of these I shall mention but one or two. One of the first methods for the determination of vanadium consisted in getting the vanadium into alkaline solution and precipitating it as ammonium metavanadate by means of ammonium chloride. This method has caused much discussion, and Gooch and Gilbert[2] did some very painstaking work to determine its accuracy. They determined that the precipitation is complete if the solution is so saturated that the ammonium chloride separates out, and the solution so saturated is allowed to stand for 24 hours. I should like to point out that the vanadium salts used in these experiments were pure, and that sodium salts, silica and the like were entirely absent, conditions which seem to make the experiment of academic interest merely and of small value to the analytical chemist.

Several investigators have tried to determine vanadium as the sulphide, either by precipitation from alkaline solution with hydrogen sulphide or by the addition of sodium sulphide and acidifying the solution with a mineral acid. The precipitate formed in these instances is an impossible colloid and represents only a fraction of the vanadium in the original solution.

Brearly and Ibbotson[3] suggest, beside the ammonium metavanadate method, the determination of vanadium by precipitating a dibarium vanadate from an alkaline solution, which vanadate may be ignited and weighed. The insurmountable obstacle here seems to be as in the case of lead vanadate, Prescott and Johnson[4], that the compound is not of constant composition.

The same authors also state that it has been proposed "to weigh the carbon dioxide evolved on reducing vanadium pentoxide with oxalic acid."

Koppel and Goldmann[5] have shown that the action of oxalic acid upon vanadic salts gives hypovanadic salts and vanadyl oxalate. It does not seem clear that these products are formed in any definite ratio, and it is a fact that the reduction of numerous samples of a standard vanadyl sulphate solution with oxalic acid gave results which were so widely different that they were of no value, and no result was obtained which agreed with the true value as determined by standard methods.

The mercurous nitrate method of Rose should be mentioned as a standard method involving serious difficulties. As given by Treadwell[6] the silica would be weighed as vanadium pentoxide. The removal of the silica is a tedious procedure, but unless it is removed there is a very strong probability that a portion of it at least will be precipitated with the vanadium. Moreover, the vaporization of mercury is not an easy matter, as is well known, and unless the quantity of vanadium pentoxide in the assay is very small, the result is apt to be high on account of the traces of mercury remaining in spite of the heat applied.

The modification of Roscoe's lead-vanadate method,[7] in which the final acid solution containing the vanadium is evaporated and the residue weighed as vanadium pentoxide, is not altogether satisfactory. The lead cannot be entirely removed with hydrochloric acid, and the evaporation of sulphuric acid is unpleasant as well as difficult. The safest procedure is to precipitate the lead with hydrogen sulphide from a hydrochloric acid solution, and the opportunities for error here are too well known to require discussion.

Colorimetric methods have been advocated, but do not seem to have met with an enthusiastic reception.

The reduction of vanadium by means of the halogens has been very carefully worked out, and the investigators[8] seem to be unanimously of the opinion that the results are accurate. The care with which the work must be performed and the length of time required seem to be obstacles which will forever prevent these methods coming into general use.

(To be continued.)

The New Ozone Purification Plant of the Water Works of St. Petersburg.

By Dr. G. Erlwein.

The City of St. Petersburg, in Russia, has built a large ozone purification plant for their water-works to sterilize the drinking water. The special object is to combat the epidemics of cholera morbus which have occurred every year now for some time, and the typhoid epidemics which have already become chronic. This ozone purification plant has started operation at the beginning of this year.

For the water supply of the City of St. Petersburg three large water-works were formerly used, of which only the largest one, however, used sand filtration, while the other two pumped the river water from the Neva River without purification into the water supply pipes of the city.

The new ozone purification plant is used in connection with one of the two water-works formerly operating without filtration and supplies water to a district consuming daily 50,000 cu. m (13,200,000 gal.) of water. The purification of the water consists in rapid filtration with subsequent ozonization. In view of the large amount of suspended material in the water, especially when ice is in the river, the rapid filtration is combined with clarifying by means of aluminium sulphate. The Penkowaja ozone purification plant consists, therefore, of two main parts, first the filtration plant and second the ozone plant proper.

As will be seen from the diagram, Fig. 1, the river water is pumped directly from the Neva River and the suspended matter is first removed. For this purpose, before the water enters the sedimentation basins, aluminium sulphate solution is added to

the water in proper dilution according to the well-known American practice.

The sedimentation basins are shown on the left of Fig. 2. Their number is eight, and by means of pipe lines they are connected with the filter tanks shown on the right hand of Fig. 2.

The rapid filter tanks, of which there are 38, are of the Howatson systems, which is very similar to the well-known American Jewell filter. Their construction is well known, but it may be mentioned that Howatson fills his filters not with the

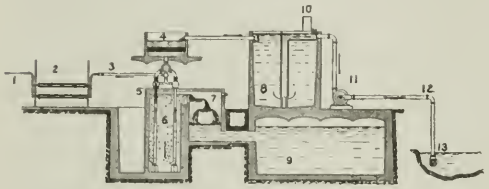

FIG. 1. DIAGRAM OF OZONE WATER STERILIZATION PLANT AT ST. PETERSBURG.

1, air pump; 2, ozonizer; 3, ozone pipe; 4, rapid filter; 5, injectors; 6, sterilization tower; 7, cataracts; 8, decantation vessel; 9, storage of purified water; 10, aluminum sulphate addition; 11, pump; 12, raw river water; 13, Neva River.

usual crushed filter sand, but with "so-called prepared silex (flint)."

The filtration speed is 4.5 m (14.8 ft.) per hour.

The purification of the filters is carried out in the well-known manner by passing filtered water back through the filter and simultaneously stirring the silex filling by means of agitating devices, which are clearly shown in Fig. 3.

The filtered water is passed through a pipe line directly to the ozone-sterilization towers. A small part of the filtered water, however, is conducted into a storage tank, which contains the

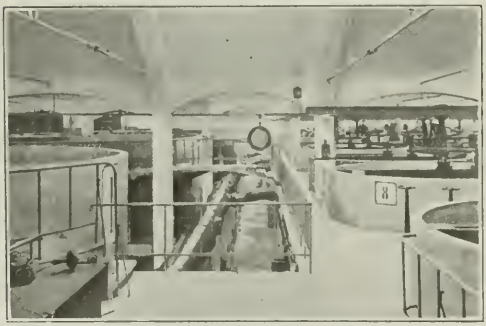

FIG. 2—SEDIMENTATION AND FILTRATION PLANT.

water used in washing the filters. While in slow filtration sand filters are expected to remove the bacteria, the rapid filters in this case are not intended to do this. Their principal object is to remove the suspended and coloring matter from the water.

As the next step after the filtration just described comes the ozone treatment proper. In the ozone plant two parts must again be distinguished, namely, the ozonizers and the sterilization towers. Fig. 4 shows the ozone plant, consisting of 128 ozonizers, and Fig. 5 shows the five sterilization towers, one of which is used as reserve. The ozonizers are of the well-known Siemens & Halske tube type (see, for instance, our Vol. I, page 179). These ozonizers change the oxygen of the air into ozone by means of high-tension discharges.

On account of the method of operation of the injector sterilization towers a relatively high value has been chosen for the concentration of ozone, namely, 2.5 grams of ozone per cubic meter of ozonized air. Before entering the ozonizers the air is properly dried by means of a refrigerating machine; this drying increases the yield of the ozone in the ozonizers.

The movement of the air through the ozonizers and pipes is accomplished by means of Otto injectors, which operate with a water pressure of 4 m (14 ft.) and suck the ozonized air from the ozonizers and drive it mixed with the water into the sterilization towers. The absorption of the ozone and the sterilization of the water occurs partly in the injectors at the top of the sterilization towers and partly in the towers in which the ozonized air rises from the bottom in a very finely subdivided state and, therefore, in very intimate contact with the water.

From the injector-sterilization towers the water is passed in cascades (to remove the air) into a pipe line which brings the sterilized water to the storage tank for pure water. From there the water is pumped by high-pressure pumps into the supply pipe lines.

For the operation of the whole plant a special electric station has been erected, containing boilers, steam engines and three-phase generators. By means of three high-frequency converters the three-phase currents produced in the generators are brought to a frequency of 500 periods. This is necessary because the ozonizers require a high-frequency current. By

FIG. 3.—RAPID FILTRATION PLANT, SHOWING STIRRING DEVICES.

means of transformers the voltage of the currents is raised to 7000 volts, which is the operating voltage of the ozonizers.

The power plant contains two steam engines, each of 150 hp, direct-connected with three-phase generators. A third machine is used as reserve. In the other parts of the plant a reserve of about 30 per cent is also provided.

With reference to the machine capacity of 2×150 hp, it is to be taken into consideration that the electric current is used not only for the ozonizing plant, but for driving the numerous motors of the filtration plant which are employed for driving the stirring devices, the filter washing pumps, etc.

The large basins, sedimentation tanks and filtration tanks are built of reinforced concrete.

As to the cost of operation experience has shown so far that if the cost of aluminium sulphate and rapid filtration is included, the cost is about 0.9 kopeken to 1 kopeken per 100 wedro (about 0.4 cent to 0.45 cent per cubic meter of water). For ozonization alone the cost is about one-half this amount. Under conditions as they exist in Germany it may be estimated that the cost of the ozonizing plant, not including aluminium sulphate treatment and rapid filtration, would be about 0.6 pfennig (0.15 cent) per cubic meter.

With respect to the physical and bacteriological purification effects, this combined rapid filtration and ozonizing system fulfills all expectations. The dirty river water of the Neva is changed into a clear and hygienically perfect drinking water. The number of bacilli spores in the ozonized water is very low, varying between 0 and 3 per cubic centimeter. Coli bacteria or pathogenous spores of cholera morbus and typhoid are not found in the sterilized water.

It may be emphasized that the city officials of St. Petersburg

are especially interested in the bacteriological effect of the ozonizing process and have appointed a committee consisting of well-known Russian bacteriologists and sanitary water engineers which supervise the operation of the works and continually control the results obtained.

Before the new commercial ozonizing plant was opened this committee of experts had made very careful experiments on the ozone treatment of water from the Neva River on a somewhat large scale in an experimental plant treating 100 cu. m

FIG. 4.—OZONIZER PLANT.

of water per hour and had thus thoroughly investigated the problem of the general use of ozone for the sterilization of drinking water, especially under such unfavorable conditions as exist in St. Petersburg.

The plant has been built for the city by the Russian Siemens & Halske Company, which has also undertaken the operation of the plant for the first years. The design and the construction of the works was made by the Siemens & Halke Company and

FIG. 5.—STERILIZATION TOWERS.

by the Compagnie de l'Ozone, which furnished the injector-sterilization towers of the Otto type, and by the Felten-Guilleaume-Lahmeyer Company, which furnished a part of the electrical equipment.

Two very large ozone purification plants for the treatment of water, each of a daily capacity of 45,000 cu. m (12,000,000 gal.) will be erected for the City of Paris, in France, within this year. The process of treating water by ozone is thus used now on a large scale to supply drinking water from a central plant, the different steps of this evolution being indicated by the plants erected in the cities of Paderborn, Wiesbaden, Hermannstadt, Florence, Nizza, Chatres, Villefranche, Rovigo, Chemnitz, and St. Petersburg. In view of this progress the doubts which originally existed, especially even among German engineers, concerning the technical and commercial suitability of the process may be considered to have been proven unfounded. It may be expected that in the future other large water-works with particularly unsanitary conditions will make use of this modern and hygienically important method of water purification.

Berlin, Germany.

The Annealing Process as Applied to the Manufacture of Malleable Iron.*

By W. P. Putnam.

To emphasize tht importance of exercising greater care in manufacturing malleable castings and to point out some of the sources of error that are so frequently found in foundries that leave the annealing process to the judgment of some individual with a "trained eye," the work of this paper was undertaken. There is no branch of the foundry business that needs a closer supervision than the process of annealing iron; no greater source of economy; no one department where greater skill is required, and yet it is safe to say that very few foundries

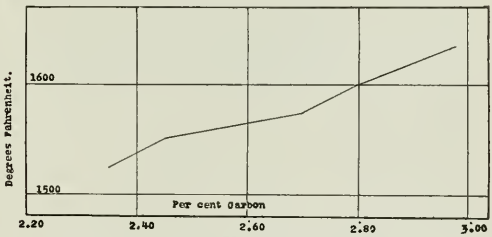

FIG. 1.—PROPER FINISHING TEMPERATURE FOR THE ANNEALING OF WHITE IRON IN RELATION TO CARBON CONTENTS.

recognize the importance of equipping their annealing ovens with proper appliances to insure a uniform product.

To call attention to the variations that can be produced in the annealing process a set of test bars was made and sent out to a number of malleable iron foundries to be annealed in accordance with their usual practice. The bars were all made from the same metal and an attempt was made to obtain a bar free from shrink or draw in the center by casting the bars with large ends. In all of the bars that were broken but very little draw was found.

The analysis of the metal poured into the bars was as follows:

	Per cent.
Silicon	0.74
Sulphur	0.041
Phosphorus	0.148
Manganese	0.24
Combined carbon	2.70

The results obtained on the annealed bars are given in Table I.

It will be noticed that in each case where too high temperatures or a long period of annealing were practiced the carbon was nearly all removed. Either practice is wasteful and produces poor malleables for some purposes.

The annealing process should be conducted to produce definite results. Metal intended for parts where machining is

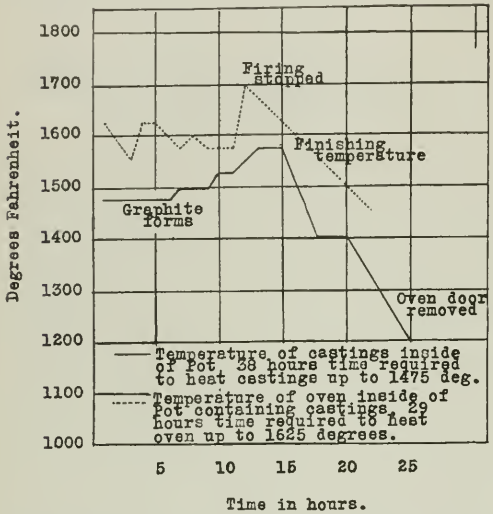

FIG. 2.—TEMPERATURE CURVE OF TYPICAL ANNEALING CYCLE.

necessary should be given a different treatment in the annealing process than metal that does not need to be machined.

To arrive at the proper annealing temperature the critical and proper annealing temperature was ascertained on a number of hard iron specimens ranging from 2.35 per cent to 3 per cent total carbon. These temperatures are diagramatically shown in Fig. 1. These temperatures are accurate within 10 deg. Fahr.

In Fig. 2 is shown the curve of a typical anealing cycle in an oven containing 14 tons of castings. The carbon in this lot of iron was 2.65 per cent. After the metal reaches the annealing temperature there is no further rise in the temperature of the metal until all of the carbon has changed into the graphitic condition. As soon as the change has been completed the temperature will rise in accordance with the temperature of the oven.

It has been found that to heat the castings much above the proper annealing temperature for a long period is not only unnecessary but a waste of fuel and produces poor castings for some purposes. After the carbon has all been changed the oven need not be fired for more than six hours. When the metal has gradually cooled to 1200 deg. Fahr. the cooling can be hastened as rapidly as desired without harming the quality of the castings.

Some of the reasons why hard and brittle castings are occasionally found may be summed up as follows:

1. Under annealing (which may be caused by too low temperature or by holding the castings at the proper temperature for too short a period).

2. Too rapid cooling of the castings after being annealed.

3. Heating anealed castings above the critical temperature to straighten without subsequent annealing.

That there is great need of the systematic handling of the annealing process is clearly evident from the results tabulated in Table No. 1. The variations shown there are typical of castings in general.

Notes on Chemistry and Metallurgy In Great Britain.

(From Our London Correspondent)

The Corrosion of Brass and Copper.

At a recent meeting of the Liverpool Engineering Society Mr. G. D. Bengough read a paper on this subject, in the course of which he stated that modern investigations indicated that for the continuous solution or corrosion of metals and alloys it was necessary that there should be in and around them substances which could form voltaic couples. There must be areas capable of acting respectively as anodes and as cathodes and also a fluid capable of acting as an electrolyte. When sea water was passing through a metal tube probably the bulk of the metal might act as an anode, the salt water was the electrolyte, but the question of greatest interest was what constituted the cathode. Lead, copper arsenide, basic carbonate of copper, ferric oxide, nickel, carbon, cuprous oxide, and even shrimps and seaweed, had at various times been stated to promote corrosion of brass and copper by forming cathodes. The presence of air was, by many chemists, considered essential to the corrosion of brass and copper by acid or saline solutions; and it was at least certain that access of air greatly increased the speed of corrosion.

Some considered that the strongly adherent green deposit frequently found on copper increased the speed of corrosion by absorption of oxygen; some thought it acted as a cathode; while others credited it with a protective action. As to the action of stray currents, it was a fact that corrosion of condenser tubes became considerably more troublesome soon after the introduction of electric lighting on board ship; but, in spite of this and of other more direct evidence, at least one well-known authority maintained that the progress of corrosion on board ship was not affected by external currents because of the very small magnitude of the current which could be conveyed by the water in condenser tubes. Now, a comparison of the magnitude of such a current with the magnitude of the currents set up by the voltaic cells previously referred to, and which did undoubtedly cause corrosion, showed that the two were approximately of the same order, and with length of time both might effect serious corrosion. It was also possible that very small induced currents might act similarly. The presence of depolarizers in the metal or liquid might exercise an important effect on the speed of corrosion, but their influence had hitherto not received much attention. Thermo-chemical action was another possible cause of corrosion, but no experimental establishment of its action had been published. The effect of increased speed of circulation of water had not yet been satisfactorily ascertained, and but little information as to the effect of sewage and other contamination of the circulating water was available.

The methods at present employed for the prevention of corrosion in brass and copper tubes were either mechanical or

electrochemical. In the mechanical class varnishes, asphalt and special cements had been tried without much success. Metallic coatings, especially tin, lead and tin-lead alloys, were better, and a particular form of ferric oxide had stood exhaustive tests on a small scale. For brass tubes the only coating now used extensively was tin, but the layer of tin was necessarily very thin—usually not more than 1/50 mm—and, therefore, very liable to pinholes and slight defects which would result either in the tin being rapidly dissolved away or in the tube being corroded more quickly, according as the tin or the tube were the more electro-positive. The efficiency of a lead coating depended on its purity, and that of a lead-tin alloy on the percentage of tin and of the impurities, while the thickness, continuity and mode of application of the layer were also factors.

Electrochemical methods consisted in the sacrifice of a cheap electro-positive metal for the preservation of the expensive one which was negative to it, for which purpose iron and zinc were generally used. It was often stated that the iron condenser casing helped to prevent corrosion of the tubes, and in some cases it certainly appeared to do so; in others it was not effective and bars of iron or zinc were placed in the water spaces at the ends of the condenser and screwed to the tube-plate; but it appeared that the protection so afforded extended only to the tube-plate and for a short distance along the length of those tubes satisfactorily connected to it.

When bars of iron or zinc were so used corrosion of the ends of the tubes should be less than it was further along, and if this were not found to be so, the meaning would be in the case of any particular tube that it was not in good metallic contact with the tube-plate, or in general that the iron or zinc was not in good contact with the tube-plate, or that the composition of the tube-plate varied too much from that of the tubes.

The protective influence of zinc had only a limited area, and in dealing with the question of the extension of that area it was necessary to consider in detail the protective action of the zinc. If no free zinc were present the brass would tend to dissolve. Brass, however, did not dissolve as such, but its zinc passed into solution to a much greater extent than its copper. When free zinc was present and a current was passing from it to the brass there was a tendency to deposition of zinc on the brass instead of solution of zinc out of the brass, yet this tendency was only slight and no appreciable quantity of zinc was actually deposited. Nevertheless, the tendency existed, and, as it constituted the protection of the brass from corrosion, if it were enhanced the protected area might be extended. The obvious means of effecting this was to pass a small and carefully regulated current from zinc to brass, keeping the e.m.f. low—2 volts to 4 volts—to avoid waste of zinc.

Progress of Electric Smelting in Norway.

The Stavanger Electro-Staalverk—a new company having a capital of £25,000—has been promoted for the electrical production of high-grade steel from the iron and steel scrap from broken-up ships. Besides the furnaces, the works at Jorpeland will include a steel foundry, rolling mills and hammers. The available energy is 2500 hp, and the annual output is estimated at 1400 tons of first-grade steel billets, 600 tons of cast steel and 300 tons of hammered steel. The Arendals Fosse Kompagni, a similar company, which has increased its capital to £233,300, is making arrangements for taking 12,000 hp from a waterfall near Arendal, and has elected to use the Grönwall process. At the Ilen Smelting Works, at Trondhjem, experimental runs, chiefly on copper, have been made in a 1000-hp electric furnace, and it is reported that the company has definitely decided to adopt electric smelting and will shortly start an iron smelting furnace to give an annual yield of 9000 tons.

British Engineering Imports and Exports.

The Board of Trade returns for January, 1911, put the value of imports of iron and steel, including manufactures, at £825,305, an increase of £110,689 as compared with January, 1910; exports amounted to £3,830,687, showing an increase of £351,815. Imports of other metals, including manufactures, were £2,247,501, an increase of £16,402, and exports, £864,988, an increase of £39,575. Imports of electrical goods were £125,805 and exports £202,996, showing increases of £16,334 and £47,922 respectively. Imports of machinery reached £433,719, an increase of £99,903; with exports £2,486,083, an increase of £385,330. Imports of new ships, £9,791, an increase of £9,688; exports of ships, £230,208, a decrease of £1,910,078.

Analytical Notes.

Separation of Iron, Aluminium and Chromium.

Tcharviani and Wunder proceed by fusing the mixed oxides with sodium carbonate in a platinum crucible for seven hours; the cooled contents of the crucible are leached out with water and the iron oxide is filtered off. In the filtrate the alumina is precipitated by excess of ammonium nitrate; the filtrate from this is acidified with nitric acid, and, after the reduction of the chromate by alcohol, chromium is precipitated as hydroxide by excess of ammonia, the precipitate dissolved in hydrochloric acid and reprecipitated with ammonia. By this method the alumina is obtained in a much purer state than either by precipitation from any acid solution with ammonia or from an alkaline solution after decomposition of the aluminate by ammonium chloride.

Estimation of Small Amounts of Lime in the Presence of Much Magnesia.

In the method employed by C. Liesse the solution is diluted to the extent of 1 in 1500 when magnesium oxalate is soluble. One gramme of the substance is dissolved in 25 parts of hydrochloric acid, and after dilution with 100 parts of water the solution is made slightly alkaline with ammonia, heated, filtered, cooled and diluted to 1500 cc. Four grammes of ammonium oxalate are added, the solution is acidified with acetic acid, well stirred and allowed to stand two hours before filtering. Good results are obtained with 99.5 per cent of magnesia and 0.5 per cent of lime.

Estimation of Chromium in Chrome-Tungsten Steel.

Henrik Wdowiszewski recommends a modification of Von Knorre's method. To one to two grammes of borings in a half-liter Erlenmeyer flask 10 to 15 cc. of a 15 per cent solution of disodic hydric phosphate and then 8 to 16 cc. of sulphuric acid, sp. gr. 1.65, and 5 cc. of water are added. On gently heating the metal dissolves in about 15 minutes; the heat is then increased and 2 cc. of nitric acid, sp. gr. 1.4, are added to convert tungsten into soluble phospho-tungstic acid. After dilution of the clear liquid with 300 to 500 cc. of hot water the addition of 3 to 5 grammes of ammonium persulphate oxidizes chromium to chromic acid. Excess of persulphate is decomposed by boiling, a little more sulphuric acid is added and the chromic acid is titrated with ferrous ammonium sulphate, the excess being determined with permanganate.

A Sensitive and Stable Litmus Solution.

A. Püschel states that the sensitive violet-colored constituent of litmus can be separated from the other coloring matter, gum and inert substances contained in commercial litmus by heating with dilute sulphuric acid—4 per cent—which precipitates it, probably as a sulphonic acid. The precipitate is collected, washed, redissolved in hot water and neutralized with sodic hydroxide. The indicator thus obtained has a violet color and is extremely sensitive.

Estimation of Sulphur in Brass and Bronze.

Gustav Thurnauer obtains excellent results by the following method: Thoroughly mix 1 gramme of filings with 6 grammes of a mixture of two parts of potassic chlorate with one part sodic carbonate; transfer to a wrought-iron crucible lined with sodic carbonate, cover with more of the fusion mixture and heat gradually until fusion is complete. When

cooled, digest the mass with hot water, filter off the oxides, acidifying the filtrate with hydrochloric acid, and determine the sulphur as barium sulphate. The author admits that the error may be as much as 0.01 per cent, and adds that if great accuracy be required a silver crucible should be used. If "an error of 0.01 per cent" mean a difference of 0.01 per cent of sulphur in the metal, the inaccuracy due to the use of an iron crucible would amount to a tolerably large proportion of the sulphur present in brass or bronze of average quality.

Market Prices.—February, 1911.

Copper, with the other metals, was depressed toward mid-month. Opening at £55.5.0 it had fallen by the 8th to £54.12.6, thence recovered gradually to £54.16.3.

Tin has again been erratic, opening lower at £195 and dropping with extraordinary rapidity to £182 by the 8th, and £171 on the 9th, recovering sharply to £197 by the 15th, and has now settled again to £193.

Lead has been stronger, being slightly lower at £13.5.0 on the 8th, recovering to £13.10.0, and closing at £13.5.0.

Iron. Hematite has been down from 67/2½, dropping to 66/1½ by the 15th. It has recovered, however, to 67/1 and present transactions rule rather lower.

Scotch Pig has also been down, touching 55/- on the 15th and 54/- on the 18th, and only recovering to 55/1½.

Cleveland Warrants are in sympathy, dropping to 48/11½ by the 15th and only showing 48/11 on the 25th.

Platinum, per oz	£8	6	6

Copper sulphate		12	6
Camphor			3
Tin ore	7	0	0
Carbolic acid			4
Para rubber		1	6
Platinum		8	0

The Camp Bird., Ltd., will in the future issue a monthly statement showing the monthly earnings of the company from its Camp Bird mine and from the holdings in Santa Gertrudis, Mexico. For the month of December, 1910, the estimated earnings applicable to profit are $112,161.

Recent Metallurgical Patents.

Gold and Silver.

Antimonial Gold Ore Treatment.—A new proposal for the treatment of gold-bearing antimony ores is made by John Jones and H. S. Bohm, of Mount Morgan, Queensland, Australia. They claim that aside from being effective for the purpose, the process also is economical by reason of the possibility of regenerating the chemicals used.

A hydrochloric acid generator and tower are part of the plant. The first treatment is with HCl, and as the ore is a sulphide the action of the HCl on the ore is to form H_2S. In another operation the chloride solution of antimony is electrolyzed, generating chlorine which is used to combine with the H_2S formed in the first instance to regenerate HCl, according to the equation $H_2S + Cl_2 = 2\,HCl + S$. The regenerated hydrochloric acid gas is returned to the tower for enriching the solutions.

The cycle of operations proposed is as follows: The pulverized ore is agitated in a dissolving vat with hydrochloric acid solution, heated by exhaust steam or other means. The generated H_2S is conducted to a regenerating chamber where it combines with Cl conducted from the electrolyzing cell, to be referred to later. When the antimony has been dissolved, the solution is filtered and transferred to the electrolyzer, fitted preferably with carbon anodes and antimony cathodes. The Cl from the cell is conducted to the regenerator mentioned above where it combines with the H_2S. The sludge from the first treatment tank contains the gold and other valuable metals, and may be treated in any suitable way, preferably by clorination. (984,090, Feb. 14, 1911.)

Copper.

Hardening Copper.—The much sought process for so hardening copper that it can be used for purposes for which it is not now fit is claimed by R. A. Hamilton and Joshua Henry, of Connellsville, Pa. The treatment enables the copper to be manipulated in the ordinary rolling or hammering processes without losing any of its stability or hardness. The hardness may be varied to any degree required. In carrying out the invention the first step is to heat metallic aluminium in a crucible to a high temperature, and add iron pyrites in sufficient quantity to form a mixture that is brittle under the hammer. The aluminium and pyrites are thoroughly mixed while highly heated, and the resulting uniform mixture poured into convenient molds. To harden metallic copper a suitable quantity of the aluminium-pyrites mixture is added to molten copper, together with a small quantity of borax and charcoal. From 1 oz. to 3 oz. of the aluminium compound is used to each pound of copper. Borax and charcoal are added in quantities of ½ oz. each. After the ingredients have been added the crucible is heated until the constituents of the molten mass have become thoroughly combined, when the metal is poured into suitable molds. (984,137, Feb. 14, 1911.)

Neutralizing Smelter Fume.—In a patent recently granted to Clarence B. Sprague, of Salt Lake City, Utah, and assigned by him to the United States Smelting, Refining & Mining Company, is described the method used at the company's plant near Salt Lake City for the purpose of removing sulphuric acid and noxious solid fume from roaster and furnace gases. It has long been known that owing to the presence of sulphuric acid in the roaster and furnace gases from copper smelters the bag-house system of condensing fume was not applicable, owing to the ready destruction of the bags. Mr. Sprague has sought to make these gases amenable to bag filtration by neutralizing the acid therein contained, after which the bag can remove the solid fume, some of which is noxious, as arsenic, and some of which is valuable, as metallic particles. His preferred means of neutralizing the acid is by introducing zinc oxide fume into the gas flues before the gases reach the bag house, although he suggests that the same result can be

accomplished by roasting or smelting with the regular charge a suitable quantity of zinc ore, which in oxidizing will give a basic element to combine with the acid element in the fume to form a neutral salt that will be without effect on the bags. By this scheme it is sought to eliminate trouble from the damage of crops and animals by the discharge of acid gases and noxious fumes onto the agricultural region surrounding the smelter. (984,498, Feb. 14, 1911.)

Aluminium.

Improved Process of Manufacture of Aluminium Alloys.—It has been found difficult to produce a composite metal containing an appreciable quantity of aluminium and having the properties of malleability and ductility. Messrs. J. G. and W. F. Mellen, of Bridgeport, Conn., have, however, recently patented a process which they claim enables them to produce an aluminium alloy with copper or other metal which does have the properties mentioned. Their process gives an alloy with lowered specific gravity and color modified by aluminium. As a general proposition it may be stated that the greater the proportion of aluminium in the alloy the lighter will be the composite metal both in color and weight and also the harder and less malleable and ductile.

In carrying out the process the copper, or other foundation metal, is weighed and melted in a pot. When the temperature has been raised to the proper point a suitable quantity of aluminium is added and immediately after it has melted a suitable oxidizing agent, such as potassium bichromate, and a suitable flux, such as borax, are added in proportions of about ½ lb. bichromate and ¼ lb. borax to each 100 lb. of alloy. A furious action ensues owing to the oxidation of the aluminium, which brings about an intimate mixture of the metals, the union of oxygen and aluminium causing atomic as well as molecular activity. The action of the borax is to dissolve the oxides as fast as they are formed, and in this way the full benefit of the oxygen is used and the objectionable oxides removed. If the oxidizing agent and flux are added before the aluminium the resulting alloy will be harder; if after the aluminium the alloy will be more malleable and ductile.

Variations in the procedure are described, but the main point to the process is the production of an intimate mixture of the elements of the alloy, a failure to obtain which has been the cause of former unsatisfactory alloys of aluminium. (982,218, Jan. 17, 1911.)

Detinning and Degalvanizing.

A cyclic method for removing tin and zinc from tinned and galvanized iron scraps has been patented by Alexander S. Ramage, of Newark, N. J. His preferred procedure is to form a solvent of sodium plumbate by dissolving lead ashes or litharge in boiling caustic soda. This solvent is contained in several tanks. Iron cages containing tin scrap are then lowered into the bath, whereupon spongy lead is thrown out of solution, being replaced by tin, forming sodium stannate. It is preferable to have several tanks of sodium plumbate solvent so that after the operation is under way the clean tin scrap is treated in the weakest plumbate solution to insure the complete precipitation of the lead, and finished in the strongest plumbate solution to insure the removal of the last of the tin. The spongy lead is sold as such for storage battery or other purposes.

The sodium stanate is then used as a solvent bath for galvanized scrap, whereupon similar reactions ensue, precipitating tin as metal and dissolving zinc, forming sodium zincate. The tin is used to make tin salts, while the sodium zincate is electrolyzed in cells, using iron anodes and thin sheet zinc cathodes. All of the zinc is not precipitated, and the solution is used for the further dissolution of lead to repeat the cycle. The inventor states that the presence of sodium zincate does not militate against the successful use of the process. (983,931, Feb. 14, 1911.)

Synopsis of Metallurgical and Chemical Literature.

Iron and Steel.

The Electric Furnace in Siderurgy.—The January issue of the *Proceedings* of the Engineers' Society of Western Pennsylvania contains an interesting and instructive paper by Mr. P. McNiven Bennie on the present status of the electric furnace in the iron and steel industries. A review is first given of the production of pig iron in the electric furnace in California and Sweden, and the principal types of electric furnaces are next sketched. The author distinguishes the following three general classes: (1) arc furnace heating by radiation (Stassano); (2) arc furnaces in which the current passes from the electrodes in the bath (Girod, Heroult, Keller) and (3) induction furnaces (Colby, Kjellin, Roechling-Rodenhauser). The different uses of the electric furnace in the steel industry are enumerated as follows: First, as to high-grade steel, of crucible quality, the electric furnace is designed to become a serious rival of the crucible method, simply because it is less expensive. Secondly, for steel castings, the electric furnace promises to appropriate to itself a considerable field. It cannot and does not aim to displace open-hearth steel castings; but for a grade of castings somewhat better than open-hearth product, cheaper than the crucible product, and for which there is even now a crying need the electric furnace has found a place in which its popularity is certain to increase. Third, the electric furnace is not claiming rivalry with the bessemer or open-hearth furnace as a steel producer for ordinary grades of structural and similar steel. Rather it is to be considered as a useful accessory or ally of the older methods. It offers an opportunity to do additional refining or special treatment in an expeditious manner secondary to other operations. As to the refractories required the author refers to the possibilities of electrically fused alumina,* making a brick that is fairly inactive chemically at furnace temperatures and this material gives great promise. Generally the roof has been short-lived in the larger steel furnaces, probably due to the chemical activity of lime, silica and iron vapors in the furnace. Any refractory material that will stand the high temperatures and prolong the life of the roof will mark another step forward. The author finally points out that in the electric furnace with a non-oxidizing atmosphere chemical reactions are possible which differ from those in the ordinary oxidizing metallurgical furnaces. He refers especially to the removal of sulphur as calcium sulphide and the removal of phosphorus as phosphide. In the extended discussions which followed Mr. P. P. Reese said that "one of our troubles is in keeping the roof on the furnace. We used a 9-inch silica brick and we tried a 13-inch silica brick and we did not get any more life out of the latter than the 9-inch. I think it is due partly to what Mr. Bennie said, the action of the lime fumes on the silica, but I think it is mostly due to the reflection of the arc. We can string the furnace roof in one heat. We do not do it as a rule, because we try to glaze the roof first. But the roof on the furnace is quite a problem just now. With our side walls we have very little trouble." The speaker appeared to hope that the fused alumina brick would solve the problems. As to the cost of power, Mr. N. W. Storer made the interesting statement that he knew of one power plant in operation at the present time where the cost of power, generated by steam, is less than ¼ cent per kilowatt hour.

Gold and Silver.

Effect of Heat on Precipitation.—At the Knights Deep cyanide plant in South Africa waste heat from the power plant is used to raise the temperature of solutions before precipitation in zinc boxes. In the December, 1910, *Journal* of the Chem. Met. and Min. Soc. of South Africa, Mr. F. D. Phillips presents figures showing the improvement in extraction due to

*See article on Alundum Refractories, page 225.

the warming of solutions, especially during the winter months.

Before Utilizing Waste Heat.

	KCN.	NaOH.	Assay value entering boxes, dwt.	Assay value leaving boxes, dwt.	Tons solution per cubic foot of zinc per 24 hours.	Temperature at head of boxes, deg. Fahr.
June, 1908	0.010	0.0140	0.331	0.033	1.58	56.4
July, 1908	0.010	0.0150	0.336	0.041	1.42	53.8
August, 1908	0.011	0.0140	0.357	0.033	1.59	57.2
Average	0.010	0.0140	0.351	0.030	1.53	55.8
After Utilizing Waste Heat.						
June, 1909	0.008	0.0140	0.412	0.010	2.08	73.8
July, 1909	0.006	0.0157	0.381	0.015	2.17	76.3
August, 1909	0.006	0.0156	0.362	0.013	2.16	77.4
Average	0.007	0.0151	0.385	0.013	2.14	75.8

It will be seen that the average temperature was raised 20° Fahr. An important point is the increased amount of solution that was precipitated per cubic foot of zinc in 24 hours and the smaller consumption of cyanide. The flow was greater and the results better with heat than without. The heated solution also was responsible for the comparative absence of white precipitate in the boxes.

Explosion in Amalgam Barrels.—The danger attending the use of barrels in grinding black sand and other rich products in cleaning up the mill is mentioned by W. R. Dowling in the December, 1910, *Journal* of the Chem. Met. and Min. Soc. of South Africa. It seems that at times gas is generated in the barrel and escapes with considerable violence when the barrel is opened. Several unfortunate accidents have occurred from this cause, even after the barrel had been opened for some time. There was still enough gas left to form an explosive mixture when ignited by a candle used to inspect the barrel and its contents.

The cause of the trouble appears to be that gas is generated when acid material containing partly oxidized pyrite is treated. The finely divided iron produced from the cast-iron barrel and the steel balls being ground in the presence of pyrite results in the formation of ferrous sulphide. Ferrous sulphide and finely divided iron acted on by the acid of the charge form sulphuretted hydrogen and hydrogen, according to the equations:

$$FeS - H_2SO_4\ FeSO_4 - H_2S$$

$$Fe - H_2SO_4\ FeSO_4 - H_2.$$

This mixture of gases is explosive, as has been proved when a barrel was inspected after opening, using a naked light. The remedy to prevent excessive pressure is to use sufficient lime with charges to neutralize the acid. Care should be exercised to open the barrel carefully, and if possible it should be possible to open it at two points so that a current of air could circulate through it and remove any collection of explosive gases. It has been found that when an excess of lime is used there is little or no pressure developed; indeed, in one instance there was a slight vacuum.

Copper.

Copper Blast Furnace Tops.—The introduction of acid making at the copper smelting plant of the Tennessee Copper Company has brought about some interesting developments in the construction of blast-furnace tops. The February, 1911, *Bulletin* of the American Institute of Mining Engineers contains an illustrated history of the developments which have led to the adoption of a special top. The article is by Mr. N. H. Emmons, of the Tennessee Copper Company.

The troubles with the old-style brick-top furnace, supported by structural steel, began when the acid plant was connected with the furnace flue and a damper put in the flue to force the gas into the acid plant. For a few months the tops were tight and worked satisfactorily, but it was then found that they would not stand the temperatures, particularly when dampered back to force the gas into the Glover towers. The steel skeleton of the top warped and became unsafe.

The first new top made was low, with brick-lined flues at each end below the feed floor leading to the main dust chamber. The top was made of 18 ribbed copper castings in the form of a grid in which firebrick were laid. The copper ribs projected above the brick and thus provided for radiation of the heat, which at times reached 1800° Fahr. to 2000° Fahr. The whole top was hung from a structural steel frame. The top of this furnace proved to be too low and allowed smoke, fume and flame to shoot out of the charging doors when opened for charging or barring.

The next attempt was similar, but the top was higher, and the flues larger. Above the floor the flue connections were made of water jackets, but these were not at all satisfactory and a connection was made to the main blast pipe and air at 45 oz. pressure blown through the jackets. This answered very well. Both of these types gave satisfaction as far as concerned the temperature of the gases and making repairs, but the gas flues were so small and low that pieces of the charge would be blown into them and cause accretions, which reduced the flue area so that gas and smoke would issue from the charging doors.

The latest development is a tubular-top furnace. It has cast-iron corner posts and dividers with walls and ends laid up with firebrick. The half-circle top is supported on 20-in. I-beams resting on the columns. All metal parts are exposed to the air for cooling. The area of the flues totals 64 sq. ft., being more than twice the area of the flues of the first furnaces constructed. This top is expensive to build, and it is thought it will be expensive to maintain.

Recording pyrometer charts are shown in the original paper giving the temperatures in the horizontal flues from two of the furnaces and at the base of the Glover towers. A peculiar point noted is that the temperature at the towers is higher than in the furnace flues. Since there must be some loss by radiation in the flues the only way to account for the higher temperature at the towers is that the furnace gases contain some unburned sulphur and carbon monoxide which, in burning in the flue, give rise to the higher temperature at the base of the towers. The temperature at the Glover tower is very uniform, showing the equalizing effect of the dust chamber. For the month of September the average gas at the foot of the Glover tower showed 0.16 per cent more SO_2 than the average of furnaces 4 and 5, and a drop of temperature of 52° Fahr. below the average of the furnaces recorded at the furnace top.

Reverberatory Furnace Hearth Construction.—We take the following description of the construction of a chrome bottom from an article entitled "Engineering in Metallurgy," by Messrs H. Schroeder and W. E. Longworth in the *Australian Mining Standard* of Feb. 1, 1911. The entire article runs through several issues and gives a complete engineering description of the works of the Electrolytic Refining & Smelting Company of Australia.

The reverberatory smelters are 34 ft. x 17 ft. at the hearth. The walls and casing plates are carried on concrete foundations 2 ft. 6 in. deep, a layer of concrete 12 in. deep being laid under the hearth. A course of red brick, laid flat, covers the concrete, and on this is placed a layer of "brasque," 6 in. deep at the center and shaped according to the template of the hearth. The brasque is a mixture of fireclay, crushed coke and sand, moistened and tamped into place. On this a 9-in. course of local firebrick was laid, followed by a 9-in. course of Scotch firebrick. The furnace walls were then built up, the first three courses being stepped out 1.5 in., the following three being stepped back, and the wall then worked straight up to the roof. By thus stepping the walls out a ring was formed to hold down the working bottom, which was a mixture of chrome iron ore and fireclay, tamped to a thickness of 6 in. in the center

and shaped according to the template, the invert being 8 in. at the center.

The chrome bottom was put on thus: Chrome iron ore, crushed to pass a ⅛-in. screen, was mixed with fireclay in the proportion of 3 to 1, by bulk. This was mixed with water to the consistency of a cupel mixture, spread over the bottom in ½-in. layers and tamped with hot irons. The resulting layer was only about ⅛ in. thick, so that 48 layers had to be put on to give the necessary thickness of 6 in. It required seven men, working eight hours per shift, 13 shifts to put in a 34-ft. x 17-ft. chrome hearth, building the sides about 9 in. higher than the center. Seventeen tons of crushed chrome ore and 3.5 tons of fireclay were used. The cost of the labor was about $170. Such a bottom, however, once made is good for all time, and there is practically no absorption.

Electric Furnaces.

The Pinch Effect for Agitation and Proportioning of Electrodes for Electric Furnaces.—A French patent of Mr. Carl Hering (French patent 419,715, June 28, 1910, under international convention, July 6, 1909) is abstracted in the *Journal* of Society of Chemical Industries, February 28, as follows: "The furnace has a bath of melted material and an electric current, proportioned with reference to the transverse section of the material is passed through a mass of molten material in communication with the bath, thus producing in an automatic manner a continuous agitation of the material, owing to the so-called 'pinch' effect. The electrode is provided with a resistance (meaning evidently the dimensions of the electrode are chosen so that it has a resistance), such that the heat developed in the electrode by the current transmitted through it is equal to double the loss of heat by conduction through the electrode when the current is not passed. (In this case practically no heat will pass in either direction through the electrode and within the furnace.) In a modified form of the process one or more arcs are introduced into the furnace between parts of the melted material."

Amorphous Carbon Electrodes and Brushes.—British patent 3336, March 2, 1911, of the British Thomson-Houston Company (communicated by the General Electric Company of this country) is abstracted in London *Electrical Engineering* of March 9 as follows: "Brushes or electrodes of increased density and mechanical strength and of high conductivity are produced by moulding from a mixture of carbon and a carbonaceous binder and baked to a temperature of 480°C. They are then impregnated with pitch or other suitable material and fired to a temperature of about 1,400°C. The following result is given as an example: apparent density, 1.66; absolute density, 2.05; porosity, 19 per cent; resistance, 0.00108 ohm per inch cube; tensile strength, 2,130 lb. per square inch.

A revolving reverberatory copper furnace has been patented by J. A. Brown, of Sydney, Australia. It consists of a barrel-shaped furnace, with firebox or gas producer at one end, and an exhaust gas chamber at the other. The exhaust gases are used to preheat air, which is conducted to the fire end of the furnace, where it is mixed with the fuel gas and directed in a blast onto the ore charge in the furnace. As the furnace revolves, every part of the charge is exposed to the heat. The charge is fed at the fire end, and the slag flows into a settler placed in the exhaust gas chamber at the other end. A tap hole is placed in the side of the furnace at its widest part, and through this the accumulated matter may be tapped.

Bromo-cyanogen as an adjunct to the regular cyanide process is prepared, according to Australian practice, by first dissolving the bromine salts in water, then adding the potassium cyanide and finally, when all the salts are dissolved, sulphuric acid is added and the mixture stirred for several hours. The charge is then ready to be added to the pulp for extraction of the gold.

Smoke Abatement Lectures at Liverpool, England.

A course of evening lectures and demonstrations for persons in charge of the furnaces of boilers and other heating appliances was commenced in Liverpool on Friday, Jan. 27. Dr. Hope, medical officer of health for Liverpool, and Professor Watkinson, professor of engineering at the Liverpool University, co-operated in arranging this course of instruction with reference to smoke abatement. The fee for the course of six lectures is 5 shillings, and 63 students, chiefly working firemen and engineers, have registered their names and are now attending these lectures. The lectures are delivered at the School of Hygiene, and are under the control of the sanitary science instruction committee of the Liverpool Corporation.

The first lecture of the course was delivered by Dr. W. L. Hawksley, one of the assistant medical officers, who dealt with the importance of pure air in relation to the health of the community and with the reforms necessary in order to obtain a purer atmosphere. Commencing his lecture with a reference to the select committees appointed in 1819, in 1843, and again in 1845 to inquire into this question, and to their findings and recommendations, Dr. Hawksley passed on to consider the reports of Dr. Lyon Playfair and Sir H. de le Beche, and the results of the first Smoke Abatement Exhibition of 1881.

The question of domestic smoke was then dealt with by the lecturer, and the connection between smoke and fog was traced and emphasized. The lecturer explained the differences between town and sea fogs as being due to the dirt and soot and tarry vapors suspended in the former. The effects of a smoky atmosphere upon health were next discussed, the differences between healthy and unhealthy persons in this respect being pointed out. The damage done by smoke to the stonework of public buildings was also touched upon, and the monetary loss this entailed was emphasized. Dr. Hawksley closed an interesting and instructive lecture by giving an account of the aims and work of the Smoke Abatement League of Great Britain, and with a summary of the speeches made by the deputation arranged by this league, which waited upon Mr. Burns at the local government board's offices in London on June 29, 1910.

The second lecture was delivered on Feb. 3 by Mr. John B. C. Kershaw, who took as his subject "solid fuels and the scientific principles of combustion."

Dealing first with the origin of solid fuels the lecturer stated that these had been formed by the decay of wood and other vegetable matter in the presence of moisture and heat, great pressure also having been gradually added to these two agencies in the latter stages of the process of conversion. An interesting table showing the chemical composition of wood, peat, lignite, bituminous coal, semi-anthracite and anthracite was exhibited, and it was pointed out by the lecturer that during the successive stages of the gradual change from peat to anthracite the carbon in the fuel increased from 52 per cent up to 94 per cent, while the gaseous constituents—nitrogen, oxygen and hydrogen—diminished in similar proportion. Reference was then made to the formation of the coal fields of southwest Lancashire and to the clear proof which existed that the basin of the Mersey was once a vast inland swamp, with a belt of forest land stretching across what is now the Mersey Bar. The remains of this forest are still to be found on the shore near the surface at Hoylake and at Formby.

The changes which occur when bituminous coal is heated were next discussed, and it was stated that the large volume of hydrocarbon gases which are liberated from this class of coal forms the chief difficulty in burning bituminous coal without smoke, since great absorption of heat occurs during this stage of the combustion process, and the liberated gases require careful and scientific management to avoid smoke formation.

The three essential conditions for obtaining the smokeless combustion of bituminous coal were stated to be: (1) A sufficiency of air supply; (2) a sufficiently high temperature;

and (3) a good mixture of the air and of the hydrocarbon gases.

It was pointed out that, although a Liverpool engineer, C. Wye Williams, clearly demonstrated that these conditions were absolutely necessary 70 years ago, the designers and builders of boiler furnaces to-day still too often neglected them and designed and erected furnaces in which one and often all of these essential conditions of good combustion were absent.

The causes of factory smoke were then stated to be: (a) Too little boiler power, leading to overworked boilers; (b) unscientific management of the boiler fires; (c) neglect or ignorance on the part of the designers of the furnace of the essential conditions of good combustion.

The lecturer closed by stating that all the smoke arising from the use of coal for industrial purposes might be abated, and in time gradually abolished, if those who control our works and factories would study the matter scientifically, and see, as far as possible:

(1) That they possessed adequate furnace and boiler equipment for the work required.

(2) That the furnaces were properly designed and that no cold or water-cooled surfaces came into contact with the hot gases before combustion was completed.

(3) That the boiler or furnace plant was under proper scientific control.

(4) That the firemen were well paid and were given an interest in their work by payment of a bonus for good results.

(5) That the chimney top was visible from the firing places of the furnaces or boilers.

The lecture was illustrated by experiments.

The third lecture of the series was delivered on Feb. 10 by Mr. Kershaw, his subject on this occasion being the examination of the waste gases and control of the combustion process.

Prof. Watkinson, Harrison professor of engineering at Liverpool University, delivered the fourth of the lectures for stokers and others interested in furnace management in the Lecture Theater of the Walker Engineering Laboratories at Liverpool, on Friday evening, Feb. 17, taking as his subjects, the setting and construction of boilers and furnaces, and the methods of producing natural, forced and induced draught.

After a few opening remarks dealing with the general aim and purpose of the lectures, and with the importance of accurate measurements of draught, temperature, pressure and of the composition of the exit gases as an aid to good work in boiler management, the lecturer dealt with the three conditions (see lecture II above) requisite to obtain good combustion of solid bituminous fuels and showed experimentally how essential these were to smokeless combustion.

The details of construction of internally fired or Lancashire boilers were than illustrated by aid of lantern slides to prove the difficulty of obtaining smokeless combustion due to the small furnace and to the arch of water-cooled plates over the furnace grate. The purpose of the bridge in this type of boiler was then discussed, and it was proved that it produced eddies in the gases as they passed over it into the flue beyond and therefore tended to promote mixture of the hot air and hyrocarbon gases given off from the burning fuel. A high bridge was, therefore, better than a low one, if sufficient draught could be obtained to work the boiler fires with it. In the absence of good draught the use of steam jets was often resorted to in order to (1) increase the air supply, and (2) to promote the better mixture of the air and furnace gases.

In the Bellville type of marine boiler air at 30 lb. pressure was employed in place of steam, and the Howden system of forced draught was now generally employed for marine work, but this system has not been adopted to any extent for boiler installations on land.

Natural draught produced by a chimney rarely exceeded ½ in. to ¾ in., measured by a water gage. This low draught limited the thickness of the fires and rendered it exceedingly difficult to keep the fuel on the furnace bars free from holes. For good combustion with thick fires, on the other hand, forced or induced draught was essential, and this was now generally recognized and adopted.

The different methods of obtaining artificial draught were then discussed and the comparative advantages of steam jets, air jets and fans were dealt with by the lecturer. As compared with steam jets, fans were more costly to install, but saved largely in running costs—a good fan requiring only 5 per cent of the steam produced in place of the 10 per cent to 12 per cent used by steam jets. Makers' statements that steam jets only consumed 3 per cent of the steam were said to be absolutely inaccurate.

The different methods of furnace construction and the use of firebrick arches for conserving heat and promoting good combustion were then dealt with. It was pointed out that a firebrick arch, by increasing the heat of a furnace, may actually increase smoke production, owing to the greater rapidity with which the hydrocarbon gases will be evolved from the newly charged fuel, unless precautions are taken to greatly increase the air supply at the same moment.

The Dutch-oven type of furnace construction for Lancashire boilers was condemned by Professor Watkinson, because from 40 per cent to 60 per cent of the heat transfer in this type of boiler is by direct radiation to the plates from the glowing solid carbon lying in the bars of the grate and this radiation can only occur to the full extent when the furnace is inside the boiler. Luminous flames radiate heat also, but not to the same extent as glowing solids. Although steam boilers can be worked efficiently with gaseous fuel they require to be specially constructed for this duty, and no ordinary type of boiler will give high efficiency with external furnaces or with producer gas. The use of economizers was finally discussed and the two chief types were described.

The lecture was illustrated by numerous experiments and lantern slides and was followed by an exhibition of apparatus for making draught, temperature and other measurements incidental to good boiler management.

On Wednesday, Feb. 22, a large number of the members of the class paid a visit to the boiler installation at Messrs. Bibby's Seed-Crushing Works in Liverpool, under the guidance of Mr. Kershaw and Chief Smoke Inspector J. Macaulay.

A Novel Development in Laboratory Burners and Furnaces.

By Chester G. Fisher

No piece of apparatus has become so commonplace in the laboratory as the burner, yet it has gone for years practically unaltered. This is really remarkable, when we consider that thousands of chemists and metallurgists have time and again tried to "push" the burner in an endeavor either to hurry an operation or to obtain a little higher temperature than the design of the burner permitted. It has remained for Dr. Méker, a French scientist, to question the use of the Bunsen burner and to prove it both inefficient and extravagant.

The ideal burner must produce the hottest flame possible with minimum consumption of gas, which flame should also be homogeneous. In order to do this, problems similar to those which present themselves in the gas engine must be solved. First, the valves and passages must fill the cylinder with a homogeneous mixture of gas and air in the proper proportion for perfect combustion. Second, all obstacles which retard the operation must be done away with, in order to allow the burnt gases to quickly pass off and the cycle to be repeated immediately.

A study of perfect mixtures soon showed quite a difference in the proportion of air, depending upon the kind of gas used, which settled the fact that burners of different designs must be used for artificial, natural and gasoline gases. A burner with an adjustable gas supply, such as a needle valve, would

not do, as the proper adjustment would be guesswork; furthermore such a valve would throttle the gas supply badly. Experiments proved that six parts of air to one part of coal gas made a perfect mixture, while the proportion prevailing in the ordinary Bunsen burner was two and one-half parts of air to one part of coal gas.

It might be explained that six parts of air to one of coal gas could not be used in the Bunsen burner, as this is a highly explosive mixture and the flame instantly "fires back." The lack of sufficient air for complete combustion in the Bunsen burner accounts for the cold cone in the center of the flame, as the extra air necessary is only obtained on the outside of the flame.

Dr. Méker, after experimenting with innumerable designs and after much painstaking work, finally perfected a burner using the perfect mixture. In his burner the gas enters the bottom and the air at the sides through many large inlet holes, the

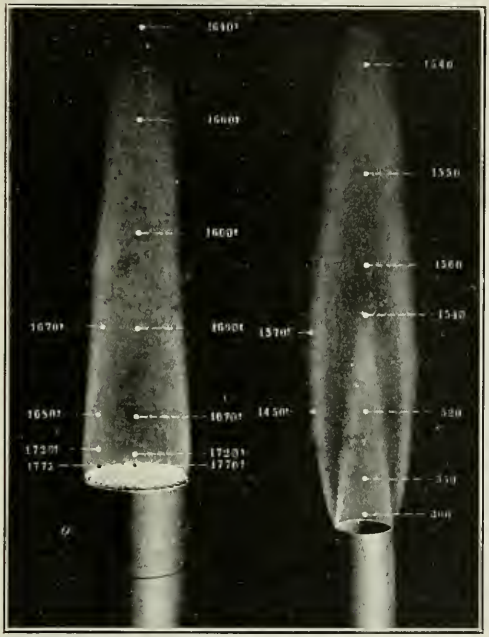

FIG. 1.—COMPARISON OF MEKER BURNER AND BUNSEN BURNER

two are thoroughly mixed in the special shaped tube and pass up at a high rate of speed. The "back firing" of the flame is prevented by a nickel grid at the top of the tube; this grid is about 10 mm thick and has openings about 2 mm square. The openings being large do not impede the flow of gas, yet the flame cannot flash back, as the deep grid is comparatively cool on account of its depth.

The result is a large homogeneous hot flame made up of numerous small flames, and the unusual effect is noted by comparing the temperatures of the different parts of the Méker flame with that of the Bunsen flame, as shown in Fig. 1. The temperatures given in this photograph were measured with a Le Chatelier thermo-couple 2/10 mm in diameter.

It will be observed that the coldest part of the Méker flame is hotter than the hottest point of the Bunsen flame, that the Méker flame is almost uniform, and that the same very high temperature prevails across the large diameter of the flame. The uniform flame produced by the Méker burner has still another great advantage in that it does not produce irregular expansion in glass or porcelain vessels being heated and, therefore, greatly reduces the risk of breakage. From the above photograph one can readily understand why a large-size Méker burner will replace a Bunsen blast lamp.

Dr. Méker was not satisfied with designing the improved type of burner but also designed an equally efficient furnace with which to use these burners. The combination of an ordinary Méker burner and a Méker crucible furnace enables gold, silver and copper to be melted without the aid of compressed air and this is done as readily as water is boiled with an old-style Bunsen burner.

It naturally followed that if such a large increase in efficiency could be obtained without blast an equally large increase could be shown over the Bunsen blast lamp when compressed air was used with the Méker burner. Dr. Méker also designed along the same scientific lines a burner using compressed air, with the result that this burner of ordinary size melted 105 grams of platinum in 17 minutes.

In combining the Méker blast burner with a furnace it was found that special high refractory clay had first to be prepared for use in lining the furnaces.

Melting Gold, Silver and Copper Without Blast.

Fig. 2 shows a plumbago crucible, which has been heated in a specially designed furnace, wherein the flame from the Méker blast lamp is made to circle around the crucible. The plumbago crucible (Fig. 2) shows the blistered effect due to the boiling out of the clay used in its construction. The four

FIG. 2.—TEST OF PLUMBAGO CRUCIBLE.

pyrometric cones shown beside the crucible were in it when it was heated. It is seen that three cones have fused, including one melting at 1770° C., and the only one standing had a fusing point of 1810° C.

The results of official tests made by the Société Technique de l'Industrie du Gaz are as follows:

Test No. 1: Consisted of measuring the consumption of gas necessary to bring to a boiling point 6 liters of water, with a Méker and with an ordinary Bunsen burner, both regulated to about the same gas consumption per hour. With the Bunsen burner the boiling point was reached after 27 minutes, 40 seconds, and the total consumption of gas was 305 liters. The Méker burner heated the same volume of water to a boiling point in 22 minutes, 30 seconds, and consumed 223 liters of gas. This shows a result in favor of the Méker burner of 23.3 per cent in time consumed and a saving of 36.7 per cent in gas by the use of the Méker burner.

Test No. 2: Consisted of bringing a crucible up to a high temperature, at first with a Bunsen blast lamp (gas and air), afterwards with an ordinary Méker burner without air blast. The temperature obtained in both cases was 1060° C. The Bunsen blast lamp consumed 543 liters of gas, while the Méker burner consumed only 273 liters. The temperature obtained was measured with a thermo-electric couple and a standardized

galvanometer. This shows a waste of 98 per cent in gas consumption by the blast lamp over the Méker burner, with considerably less labor for the operator of the Méker burner and greater regularity of temperature, arising from the discarding of the air blast.

Other burners of different shapes and designs are made, in order to meet the conditions ordinarily found.

In view of the large amount of work done by Dr. Méker in perfecting these burners, it was very fitting that the Société Technique de l'Industrie du Gaz concluded its report as follows: "Considering that the burners of Dr. Méker permit of working in ranges of temperature formerly impossible to obtain, and thus contribute, both in the laboratory and in the industrial world, to the increased usefulness of gas, the committee has decided to reward the inventor by awarding him the diploma and silver medal of the society."

These burners and furnaces are now placed on the market in this country by Dr. Méker's American agent, the Scientific Materials Company, Pittsburgh, Pa.

Thermit Repairs of Caustic Pots.

By Thos. M. Skinner, Jr.

In the repairs of caustic pots by the thermit process it is of great importance that an alloy be used which will not be affected by the sodium hydrate which is fused in these pots, and for this purpose I find 50 per cent ferro-silicon to be very satisfactory, as it makes the thermit steel in the weld resemble the cast iron of which the pots are made. In using ferro-

FIG. 1.—CAUSTIC POT SETTING, DIRECT FIRED WITH SLACK COAL.

silicon, 3 per cent based upon weight of thermit has proved the most satisfactory proportion.

Defects in these alkali pots usually develop at a distance about one-third up from the bottom, where the heat is chiefly applied. This position makes it very difficult to place a form to handle the thermit pour. An additional form is necessary on the outside of the pot amply large to cover all possibilities of the thermit spreading in its molten state and thereby missing the form.

A very good method which has been tried and found successful is to build the inside form in which the pouring is made by filling the hole as usual with wax; then as the pot is of circular shape, take a piece of asbestos (½ in. thick) cut about ½ in. larger than the hole to be mended and laid over wax and hole; then places are cut for pouring hole, riser, and preheating hole as wanted and wooden plugs placed where said holes are desired. Then the form is filled with fireclay, pounded firebrick and sand in equal parts. The wax is melted out by a torch and is caught below as it comes out of preheating hole. The sheet of asbestos serves not only to keep the fireclay from making an uneven surface, but gives a clean, smooth job without any slag adhering, which would compel a great amount of chiseling afterwards.

By this thermit process of mending our caustic pots we have been able in many instances to make worthless pots practically as good as new, thereby extending in a very economical way the life and usefulness of these pots.

Green River, Wyo.

The Development and Varied Application of Oxygen Rescue and Reviving Apparatus for Mines, Metallurgical and Chemical Works

By Dr. Henry M. Payne.

When the need of conveniently portable rescue apparatus first became apparent in the mining districts of Europe several types were developed, in all of which great difficulty was experi-

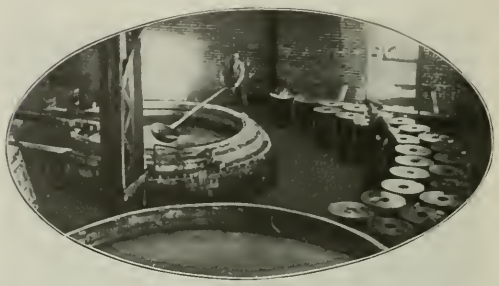

FIG. 2.—CAUSTIC POTS BOILING, SHOWING METHOD USED IN HANDLING HOT CAUSTIC INTO DRUMS READY FOR SHIPMENT.

enced in preparing a regenerator whose chemical action should provide for perfect absorption of CO_2 and at the same time maintain a temperature sufficiently low as to cause no discomfort to the wearer either from exterior contact with the apparatus or from hot air provided for respiration.

In the early forms a fluid solution containing caustic potash was used. The oxygen was exhausted from the bottle by the efforts of the wearer. The next improvement was the use of

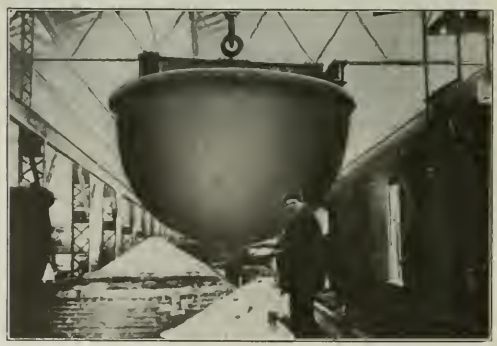

FIG. 3.—CAUSTIC POT BEING LIFTED BY ELECTRIC CRANE IN PREPARATION TO A THERMIT POUR.

flax or cotton waste, which was saturated with the regenerating compound and the compression of the oxygen into iron tanks. The great danger in both these equipments lay in the wearer's inability to regulate the flow of oxygen and to avoid a cumbersome regenerator of irregular and uncertain capacity.

The first type to merit general recognition outside of Austria had a regenerator for which the filler had to be prepared

at the time the apparatus was to be used, a proceeding which entailed great delay and serious loss of life, since it is a well-recognized fact that such apparatus is of the greatest service only when it is immediately available upon the first advice of a catastrophe involving loss of life from asphyxiation of any kind.

Attention was then directed to the preparation of a regenerator whose absorptive capacity should be constant for a given period, and which could be sealed and delivered in perfect condition at any point, ready for immediate use on breaking the seals.

This having been accomplished, effort was concentrated toward providing the maximum area of absorptive surface in order that less heat should be generated and so that a cooler, hitherto necessary, could be dispensed with.

Various shapes of oxygen bottles were tried, but it is now the practice to use the standard cylindrical type so common in all medical apparatus utilizing oxygen.

The elimination of reducing and by-pass valves and the continued simplification of the apparatus has eventually evolved a complete, light weight, "foolproof" and thoroughly reliable form, known as the Westfalia Rescue Apparatus. This type is largely in use by the United States Bureau of Mines, having recently been furnished for the Rescue Station at Pittsburgh and the new station at McAlester, Okla., and on several of the Mine Rescue Cars now being equipped for use in Wyoming, Missouri, Oklahoma, Arkansas and Pennsylvania.

The Illinois Mine Rescue Station Commission are likewise equipping their new stations and three cars with a number of sets of this type.

Until very recently the helmet was supposed to be a necessity, but the Westfalia mouthpiece type now on the market has proved equally safe and possesses many advantages over the helmet.

Earlier and all other types of helmet depend upon the inflation of pneumatic pads for making a tight fit around the face and head, whereas in the Westfalia apparatus an elastic face washer is provided which fits any inequality or irregularity and enables any person to wear the helmet without the usual difficulties of securing a good fit and renders its continued use a matter of no discomfort. These face washers are also provided with an inflating bulb and pneumatic pad, but the safety of the helmet in no wise depends upon the pneumatic pad, since even if it is punctured or the rubber old and weak, the face washer continually conforms to the head and has no angles or creases. It is also easily removed from the helmet and replaced.

The mouthpiece type referred to may be instantly substituted for the helmet and requires no change of apparatus. The nose clip, whose chief danger lies in the laceration of the nose, or its accidental removal by sneezing, and general discomfort, is also obviated with the Westfalia mouthpiece and in its stead cotton plugs, dipped in vaseline, are inserted in the nostrils and an ordinary guard worn over the nose.

A speaking diaphragm attached to the mouthpiece enables the wearer to carry on conversation without difficulty. The regenerators are also furnished in one-hour, two-hour and three-hour types, so that for practice purposes the smaller ones may be used, while in emergencies the three-hour type provides 50 per cent greater capacity than any other. These regenerators being curved to fit the back, the framework leaving an air space between, and the total thickness being reduced to a minimum, the wearer is enabled to crawl through a smaller space than has heretofore been possible. They are also made interchangeable, thus affording owners of older types of other makes of apparatus all the benefits to be derived from the improved regenerator.

The field in which this apparatus is used is not confined to mines, but is also rapidly extending to chemical works, smelters and in extinguishing fires where dense or dangerous gases, smoke or fumes are encountered.

Not less worthy of consideration is the reviving apparatus which is applied to persons asphyxiated by gas or overcome by smoke or water, and which is so commonly used in hospitals for extreme respiration. In this, also, simplicity has been the aim and the "Dr. Brat" system is supplied in a light portable case ready to be instantly and intelligently applied by any person who can read the indices on the operating lever.

Until very recently such apparatus was operated by clockwork, but the chief objection to this lies in the fact that an unconscious or semi-unconscious person breathes in gasps and with extreme irregularity, and any attempt to force oxygen into or exhaust smoke or gas from the lungs with clockwork regularity must inevitably tend to choke the patient. By eliminating the clockwork attachment a light breathing bag is provided for observation and the inhalations and exhalations of the patient are assisted by a slight movement of the lever, which first exhausts the lungs and then injects oxygen, both of which processes are performed under any desired pressure or vacuum up to 2.5 atmospheres.

All this apparatus is on exhibition at the offices of the Westfalia Engineering Company, 42 Broadway, New York City.

Alundum Refractories.

The development of electrically-heated laboratory apparatus has been very great during the last two years, and to meet this demand the Norton Company, of Worcester, Mass., and Niagara Falls, N. Y., has been making use of the refractory qualities of its abrasive product, alundum, made up into the

FIG. 1.—ELECTRIC FURNACE PARTS OF ALUNDUM.

various shapes required in crucible, muffle and tube furnaces. This has led them into other lines, and now this company is offering a general line of alundum refractories of a high grade, comprising not only the articles for winding with high-resistance wire, but also general utility muffles, crucibles, furnace parts and bricks.

The properties which have made it superior for these pur-

FIG. 2.—ALUNDUM TUBES.

poses are high melting point, high heat conductivity, low coefficient of expansion and resistance to chemical action.

Alundum is fused aluminum oxide and is made by melting and purifying the mineral bauxite in a special electric furnace, which, together with the process of manufacture, has been described before in this journal. It is primarily an abrasive material, but the properties mentioned above make it useful as a refractory. There are several grades for abrasive pur-

poses, but only two of these are used in this work. A white product having less than 1 per cent of impurities is used in all the smaller articles, while a brown material with 6 to 8 per cent of impurities is used in larger shapes and in bricks.

The articles so far turned out are mostly porous, consisting as they do of more or less finely-divided grains, held together by a ceramic bond. This porosity renders them unfit for any work in which a gas-tight chamber is required, but on the other hand is very advantageous in another way, for the porosity can be varied to such a degree that crucibles and dishes may be used for filtering purposes. The Gooch type of crucible works perfectly on all precipitates met with in analytical work. It is a great time saver in the laboratory,

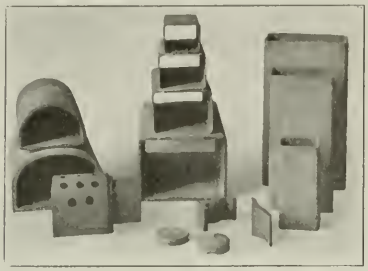

FIG. 3.—ALUNDUM MUFFLERS

as it does away with burning filter papers or preparing asbestos blankets. The crucibles are quite unattacked by aqueous acids or alkalies, so that almost any analysis may be made in them safely.

The mufflers last from four to five times longer than the ordinary fire-clay type, when used in a gas furnace, and when wound with resistance wire are almost the only kind that can be used. The builders of this latter type of furnace use alundum cores exclusively in all shapes and sizes of furnaces.

Combustion boats made of alundum may be used repeatedly in steel-works analysis, as the oxidation products do not stick in the boat or attack it. If other boats are used they may be protected by a layer of carefully-prepared carbon-free alundum grain, which is put up in convenient-sized packages.

Alundum cement may be used for lining crucibles and small furnaces, as it has the same composition and refractoriness as the made-up forms. It is sold, ready for use, except for moistening with water.

The crucibles of denser structure may be used for melting metals but are attacked by slags. The melting point being

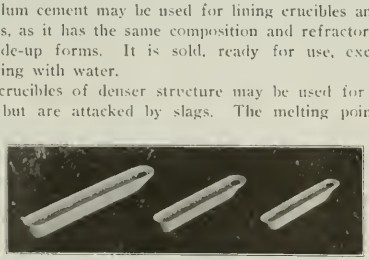

FIG. 4.—ALUNDUM COMBUSTION BOATS

very high, about 1950 deg. C., and also sharp without gradual softening, makes them especially well adapted for melting the metals of the platinum group, and the purity of their composition renders the melt free from contamination.

Bricks have been made experimentally, but the high cost of manufacture and their great weight makes them available only in special cases. For roofs of electric furnaces they are well adapted, on account of high melting point and low coefficient of expansion. Some trials have been made and others are under way to thoroughly test their value for this work. Announcement will be made of the outcome of the trials when they are completed.

Some attempts at casting alundum articles from the molten state have resulted in partial success. On account of the extreme difficulties in the way, only tubes and small crucibles have been prepared, and these are rather crude in appearance, the hardness of the product making it well-nigh impossible to work them into any smoothness after they are cast.

Fig 1 shows various electric furnace parts made of alundum. The high thermal conductivity has here the advantage that the heat generated in the resistance wire is conducted away so rapidly that overheating and consequent burning out of the resistance is prevented. At the same time the chemical inactivity prevents corrosion of the heating wire. By the use of alundum cement, the element can be completely encased, preventing oxidation and corrosion.

Fig. 2 shows a variety of alundum tubes for high-temperature electric-furnace work.

Fig. 3 shows a variety of alundum muffles for furnaces heated by electricity, gas or gasoline. These alundum muffles last from four to six times as long as the ordinary clay muffles.

Fig. 4 shows alundum combustion boats, which, while adapted to any kind of combustion work, were especially designed for the determination of carbon in iron and steel. The pure alundum of which they are composed does not react with the iron oxide of the sample, and the boats can be used repeatedly.

A large display of the shapes already made will be on exhibition at the Chemists' Club, in connection with Mr. L. E. Saunders' paper at the April meeting of the American Electrochemical Society, and some demonstrations of the advantageous properties will then be arranged. The variety exhibited will show the possibilities of moulding, and special shapes may be made to order, of almost any degree of intricacy.

The articles are on sale at the Worcester, Mass., plant of the Norton Company, and descriptive literature and price lists will be sent on request.

Fused Quartz and Quartz Glass.

By Charles Colne.

From time immemorial quartz has occupied a well-known and useful position in the manufacture of glass. In the shape of white sand or quartz crystals it enters in the proportion of about 60 per cent in the composition of the different qualities of glass, for bottles, windows or hollow ware. Lime, potash and soda are used in order to obtain a fusion at a low temperature, bordering on 1300°, to treat the mass in a refractory furnace heated by coal or gas. Such additions, however, alter the qualities of quartz.

It has been discovered long ago that in melting quartz alone at a temperature above 2000° a transparent body is obtained which is insoluble in acids and is an insulator of a superior quality to common glass. Such a product, sometimes erroneously called quartz glass (because it is not glass, but pure silica), has been manufactured commercially for several years with the oxyhydric blow pipe or in the electric furnace. Before these processes reached a practical point inventors found themselves beset by many difficulties. The methods used were very complicated and it is only since the World's Fair of 1900 that anything like success has been reached, as was shown when the firm of Schott exhibited quartz plates produced by fusion.

Inventors were then restricted to the use of the gas blow pipe as the only means of obtaining the needed temperature. Mr. Shenstone's process was to heat Brazilian quartz to a very high temperature, then throw it into water. Crystals would then divide into small fragments; these were agglomerated

in the shape of rods and fused by the blow pipe into thick thread. These threads were wound up spirally around a large platinum thread and again submitted to fusion, producing small tubes of regular shape. These tubes closed at one end, were drawn out and blown into small balls with which small capsules and bulbs were made.

This method later on was improved by preparing directly small, thick, short tubes in an iridium or zirconium capsule, then drawing and blowing them. The cost price of such articles was very high, as high as $110 per pound. Moreover, these objects had very thin sides, were very frail and of necessity of restricted dimensions. They were, however, very transparent—of a transparency that could not he reached with other processes.

Dufour, Callender and Le Chatelier in their experiments have shown that the fusing point of quartz is very near its ebullition. This explains the difficulty of working the melted mass, or more properly, the pasty mass of quartz which has passed from the crystalline state to the amorphous state. A melted mass of this nature shows a tenacity like that of hot asphalt and work must be carried on rapidly, as when the source of heat has been removed solidifying takes place at once. Such extraordinary viscosity almost prevents the expulsion of bubbles which are formed during fusion. In order to get rid of these bubbles a preliminary baking or fritting of the quartz is necessary. Other efforts have been made to obtain fusion under pressure, but apparently with no practical results.

It is only since 1901 that the first attempts have been made to make glass in the electric furnace. A German firm, Becker & Company, of Berlin, appears to have been among the first to make such trials. Since that time these furnaces have been much used for making quartz glass and the result has been to develop the different methods now in use. The active part of a blow-pipe flame is in fact too restricted to allow large quantities of quartz or quartz glass sand to be treated. As soon as the mass to be treated exceeds a few pounds a mass is obtained without transparency looking like porcelain.

The electric furnace did not give satisfactory results either in the first experiments. Trials made to melt glass sand with an arc furnace resulted in getting ingots of glass as large as a fist with a silvery iridescent surface. To bring such ingots to the shape of a receptacle the resistance furnace had to be brought into play. The product, however, was impure owing to the contact of the quartz with the carbon electrodes and the objects made were covered with a coat of silicate of carbon.

Since that time it has become possible to melt white sand completely in the resistance furnace of Borchers. The quartz blocks obtained are drawn so as to make opaque tubes long enough and free from impurities. This process consists in using a furnace in which in a space left vacant between the terminals is placed a tube of thin carbon perforated like a sieve and surrounded by the sand; this tube is heated by the current passing through it and fuses the quartz. Compressed air is then forced through this tube in order to expand the quartz cylinder which has been formed against the sides of an appropriate mold.

The quartz so melted, owing to the high temperature of the incandescent carbon, passes from the crystalline to the amorphous state. It is capable of standing a very high temperature and has a very high insulating power; but it is opaque and slightly inferior, in resistance to sudden changes of temperature, to quartz glass melted with the Shenstone and the Heræus blow pipes. However, the latter process cannot make large pieces fit for industrial uses.

A German company has succeeded in producing transparent quartz glass by the following process in the electric furnace: The sand of the glass maker is introduced into a carbon cylinder, used as a crucible, in the center of which is placed a rod of carbon heated by the electric current at the same time as the outside cylinder. Starting with glass sand, of ordinary quartz, a complete fusion is reached, which, when renewed several times, will produce a transparent mass. To work the latter with a view of getting small objects for laboratory use this can be done either in an electric muffle or with the oxy-hydric blow pipe.

As the fusion of quartz and its transformation into the amorphous state require much heat these two successive operations produce objects more rapidly and more economically; the blow pipe serving only for fining and working the already melted quartz in the shape of tubes. Large pieces are blown in a special manner. Instead of using compressed air or steam, which requires a preliminary preparation, or the introduction of the dose in the quartz bar, which is a difficult operation, owing to the rapid solidifying of the mass, there is introduced in the quartz block by the opening left by the central electrode a moistened body which is transformed into steam—some green wood, for instance, or a substance such as marble, which at the high temperature to which it is subjected decomposes and liberates a gas. During that time the ends of the block are held by pincers. The liberated gases force the quartz against the sides of the molds having the desired shape. The mass when solidified is withdrawn from the mold and the objects are then cut to the desired dimensions with diamonds or by fragments of carborundum mounted on disks of copper or zinc. They are then polished.

To strengthen the objects obtained the tubes can also be blown into metallic woven fabrics. It is with such a process that large capsules of 120 in. are obtained for evaporating, and tubes more than 40 in. long and 10 in. in diameter for use as receptacles for acids. The product thus obtained can be substituted for china and stoneware.

The properties of quartz glass have been investigated by sundry experimenters, especially by Le Chatelier, Shenstone and Gaurties; all have shown how raw quartz not melted is sensitive to variations of temperature; when heated suddenly it breaks in a number of fragments. Fused quartz, on the contrary, which has passed from the crystalline to the amorphous state, resists quite well such changes, especially in a thin shape. Its coefficient of expansion is about 0.0000007 per degree Centigrade, much less than that of platinum. It is interesting to note that the expansion of rods of quartz is quite regular up to 1000° C., but ceases at 1200° C., and at higher temperatures a contraction takes place. The softening point is near 1700° C., the fusion point 2100° C., and at 2200° C. exaporation starts.[1] Its specific weight varies from 2.1 to 2.2.

Quartz is an excellent electric insulator, plates of 1.5 mm to 2 mm thick cannot be pierced except at a tension near 35,000 volts. For a thickness of 7 mm more than 70,000 volts are required.

Being insoluble in acids it makes it applicable to many purposes. It is, however, attacked violently by hydrofluoric acid and slightly by hot phosphoric acid. It does not resist either alkalies. Therefore, laboratory apparatus of quartz glass are sometimes coated with a resisting varnish or a coating of precious metals. The "spray" process for galvanizing, invented by Mr. Schoop (this journal, Vol. VIII, page 404), can be used for such a purpose with economy.

Quartz glass is very translucid for rays of short wave-length. Its great permeability for ultra-violet rays causes it to be used in phototherapy and in the production of ozone for sterilizing water and milk.

Applications of quartz glass are now very numerous and everything points to further extensions. Its great resistance to sudden changes of temperature renders it very precious in chemical laboratories for obtaining capsules and crucibles for making thermometers in which the displacement of zero is nil, etc. For lamp glasses, for globes, for lighting by incandescence, for supports for mantels, for tubes for levels and steam boilers. Mercury-vapor lamps are also made with bulbs of quartz glass.

[1] Others give the melting point as between 1700 and 1800° C and state that softening occurs at 1500° C.—Ed.

Non-transparent quartz can be shaped into vases of large dimensions and takes the place of stoneware with advantage in making pipes used to carry acids, lining for refrigerators and heaters. It also can take the place of porcelain or platinum for making concentration apparatus more durable and cheaper.

Quartz glass is now made by three principal firms, in England by the Thermal Syndicate, Limited, and two in Germany, the Heraeus Campany and the Deutsche Quartz Gesellschaft.

At the factory of the latter objects of large dimensions are obtained by means of a resistance furnace, made of a hollow carbon cylinder of about 200 mm diameter with a central carbon rod. The space left vacant between carbons is filled with white sand and an electric current is passed through the carbons, which are raised to the temperature of 2500°. Each furnace can make an ingot of about 50 kil. The ingot is taken out with pincers; in the hollow part is introduced a gasifying body to do the molding, as described before. The fusion-room contains two large transformers from which 18 furnaces can draw power. Around a third room are distributed the finishing rooms, such as for the treatment with sand blast, grinding with diamonds or carborundum, blowing with the blow pipe, repairing, etc.

Of late years the industry of quartz glass has increased considerably owing to new processes using the electric furnaces. The cost price of manufacture has decreased materially. Although it is yet too high to allow the sale of the objects for the same price as those of common glass of the best quality the qualities of quartz glass give it a preference in a great number of applications where its use is now a necessity.

Large Bronze Casting

The accompanying illustration shows an interesting and rather exceptionally large bronze drum casting. The drum is 12 feet long and 5 feet in diameter, and is used as the drying surface in a large vacuum rotary drum dryer. Such drums are generally made of dense air furnace iron, but in this case it was necessary to use a high quality bronze drum due to the fact that the vegetable extract to be dried on the drum would become discolored if it came in contact with the iron.

BRONZE CASTING

The mold for this casting was swept up in dray sand, the core being swept in loam. When the casting was poured the mold was in a vertical position, thus accounting for the very clean surface free from any blow holes. It required 16,000 pounds of metal to pour the casting and on account of this large quaitity it was necessary to melt the metal in a 48-inch cupola. To melt bronze in a cupola is unusual, but the Buffalo Foundry & Machine Company, who made the casting in question, has been very successful in following this practice where large quanties of metal are required.

An Experimental Arc Furnace for Fine Ore Reduction.

An exhibition of the Reid electric smelting process was given on March 9 at the workshops of the Cobalt Reduction and Refining Company in Newark, N. J. Mr. James H. Reid who some years ago was interested in the promotion of a carbon cell, has developed during the last years an arc-furnace process for the treatment of fine ores, as follows:

The ore fines are fed in a continuous stream by gravity through an electric arc. Within the arc they are reduced (as there is no reducing agent employed, as was exactly stated, the ore must have such a composition or must itself contain such elements as to make reduction possible). The particles of hot reduced metal together with the gangue drop into a box with running water. On the sudden contact with the water the particles of gangue explode and are carried away in the stream of water, while the reduced metal or alloy collects on the bottom of the box. The volatile matter in the ore, when subjected to the heat of the arc is evaporated and the vapors are sucked off from the furnace by a fan and recovered in condensers.

This process was exhibited with an experimental furnace, the capacity of which was given as 1 ton of ore for 24 hours. Exact data of cost, if working on a large scale, are not yet available. The purely electrical and mechanical part of the experimental furnace appeared to work quite nicely. The electrodes between which the arc was produced were of steel. But on a large scale when treating nickel-cobalt ore, it is proposed to use nickel-cobalt electrodes, part of the reduced alloy being used for casting the electrodes. Mr. Reid estimates that the electrode consumption per ton of alloy produced will be 660 pounds of nickel-cobalt electrodes.

The reduced alloy, which collects on the bottom of the water box, is to be treated in a separating kettle, which was shown, but not exhibited in operation. It is provided with electrodes, simply for melting the alloy. Further it is arranged so as to be rotated. The object of this is to separate the constituents of the alloy (perhaps after making a suitable addition) by specific gravity into tops and bottoms.

The company intends to build a larger plant embodying these ideas, near Cobalt, Canada.

Electric Furnace Exhibit.

The high development of the laboratory and smaller industrial electric furnace is well shown at the permament exhibition room of the Hoskins Manufacturing Company in Chicago.

The large muffle furnace for the heat-treatment of high-speed steels, shown in the very center of the photograph, is always of especial interest to visitors, due to the remarkable evenness of the "electric heat" it displays. A temperature of 2300° Fahr. may be produced and this may be regulated to a very fine point

ELECTRIC FURNACE EXHIBIT

by a simple turning of hand-screws in the power circuit. Close to this a crucible furnace, operating on the same carbon-resistance principle, is shown, capable of melting platinum.

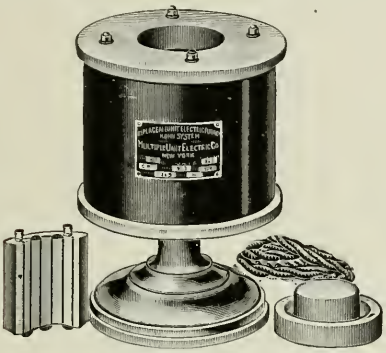
For combustion determinations of carbon in steels the new electric tube furnace, heated by large cross-section metallic elements, is exhibited. This is seen between the muffle and crucible furnaces on the table at the right.

The exact temperature of each furnace operated is clearly shown by means of a full pyrometer installation.

A Novel Laboratory Electric Furnace with Replaceable Heating Units.

We had recently an opportunity to witness a demonstration of an interesting new type of electric laboratory furnace at the workshops of the manufacturers, the Multiple Unit Electric Company, with offices at 47 Maiden Lane, New York City.

This type of furnace is built under patents of Mr. M. M. Kohn. Its chief feature is the replaceability of the electric heating units so that anyone which might burn out can almost instantly be replaced by a new one, held in reserve. The repairs

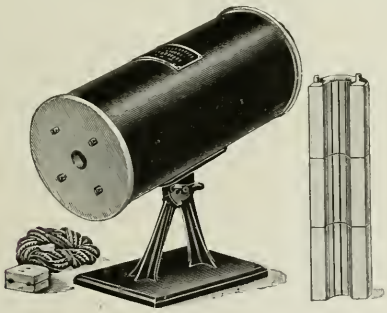


TYPE CR CRUCIBLE FURNACE

of the furnace are thus made exceedingly simple and rapid.

The housing of the furnace is built of a number of sections of a special clay, formed to meet the requirements of each particular case. They are held together by a special cement which will not crack as a result of heating and cooling. This housing which also carries the necessary electrical connections, after being assembled is placed in a metal case, together with the necessary heat resisting material, and is then sealed in permanently, as it is never necessary to remove or change it in any way, unless the furnace housing has been mechanically damaged.

In this housing certain peculiarly shaped openings are molded, into which the replaceable heating units fit, the openings being shaped according to the nature of the furnace, viz.: circular



TYPE CO COMBUSTION FURNACE

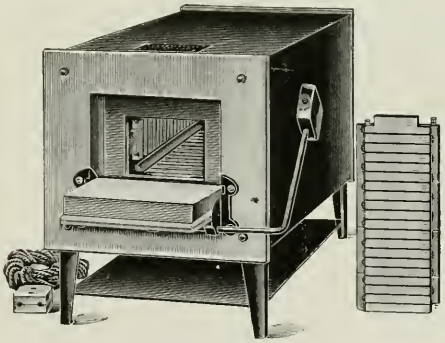
for the crucible and combustion types; and rectangular for the muffle type. The removable units which are replaced in case of a burn-out, carry the necessary heating medium, which may be wire or other material suitable for the purpose. The number of units required, depends entirely on the type of furnace, some requiring two, others four, or more.

In case of a burn-out, all that is necessary is to remove the unit which is burnt out and slide in another one, which can be done by anyone, without any technical knowledge. Units can be replaced, when the furnace is red hot, in less than ten minutes.

These units are made of special clays and other refractory materials in various forms and sizes to meet the requirements of each case. They are made in a number of sections or pieces, each of which is complete in itself and are assembled on rods of special material, which act not only to tie or hold them together, but also as the electrical conductors to carry the current from the housing to the heating medium in which the units are wound. Looking at the front of a unit a number of undercut open slotted grooves are seen, into which the heating medium (wire, etc.), is placed, which while holding it firmly in place still allows for expansion of the medium, while another very important feature of this special groove is the open slot, which allows for the full heat of the medium being utilized in the furnace chamber.

On account of the method of building up the furnace housing of sections it is easy to build the furnace in any size or shape as desired. For instance, a 4-inch furnace may be easily changed into a 5-inch furnace by inserting proper distance pieces.

Further by the method of connecting the heating units it is possible to get a uniform heat within the whole furnace, or to get higher or lower temperatures at different places, according to the requirements of the case. This latter condition must be fulfilled, for instance, in electric furnaces for the automatic heat treatment of blades for safety razors. While the blades pass through the furnace they are subjected to different tem-



TYPE MU MUFFLE FURNACE

peratures according to the requirements of the heat treatment. Quite a number of Kohn furnaces are in successful commercial use just for this purpose.

Another feature of the Kohn furnace is that it is built for direct operation on 110- or 220-volt mains without necessitating the use of a transformer. Any muffle or combustion furnace can be used on either 110 or 220 volts by simply shifting a plug from one set of contacts to another, according to the voltage that is to be used.

Any of the Kohn furnaces may also be equipped with an additional two-heat switch, by means of which it is possible to obtain ¼ heat or full heat, and also with special three-heat switches by means of which 1/3, 2/3 or full heat is obtained, both without the use of a rheostat or external resistance, and with absolute uniformity of temperature.

The safe maximum working temperature of the Kohn furnace is from 1750° to 1850° F. But in emergency cases they will stand temperatures up to 1900° F. for a short time.

The adjoining illustrations show the standard types of the Kohn furnace, the type CR crucible furnace, the type CO combustion furnace and the type MU muffle furnace. In each case a heating unit is illustrated on the side of the furnace, to show its construction.

Digest of Electrochemical U. S. Patents.

Ore-Treatment (*Continued*).

286,208, Oct. 9, 1883, Leon Letrange, of Paris, France.

Zinc. Calcines blende to zinc sulphate and passes the fumes over calamine undergoing calcination, partially converting it into a sulphate. Unsulphated zinc oxide is dissolved by dilute sulphuric acid in vessels of masonry lined with bitumen. The several vessels are successively charged with mineral and acid, drained and refilled. The zinc is precipitated from the acid solution in electrolytic cells of wood lined with glass or lead, the anodes being plates of carbon and the cathodes thin plates of zinc, copper or polished brass from which the deposit is stripped. The liberated sulphuric acid overflows through outlets at the top of the cells, the level of the bath being maintained by the introduction of fresh solution.

291,670, Jan. 8, 1884, Michel Body, of Liege, Belgium.

Gold and silver. The ore is ground fine and either treated in heaps with a ferric-salt solution or mixed with ferric salts and roasted. It is then placed in an electrolytic amalgamator, consisting of a revoluble horizontal cast-iron drum, serving as cathode and containing a number of cast-iron balls. The anodes are plates of compressed coke or graphite, suspended from a stationary, hollow, perforated, insulated shaft passing through stuffing boxes in the ends of the drum. The electshaft.

A steam pipe also does enter the electrolyte. The silver deposits on the drum and balls and is absorbed by mercury subsequently introduced into the drum. The ferric salts are simultaneously converted into the ferrous form.

300,950, June 24, 1884, Henry Benner Cassel, of New York, N. Y.

Dissolves metals, especially gold, by electrolytic chlorine. The cell is a tank containing a semi-annular sheet cathode. The tank receives the lower half of a rotary horizontal drum, containing a series of carbon rod or plate electrodes, arranged peripherally. The ends of the anodes extend through the heads of the drum and are connected by copper wires to a copper rod on one axle, making contact with a fixed copper spiral. The heads, or the cylindrical or polygonal body of the drum, may be of porous clay. Or the body of the drum may be omitted and replaced by a diaphragm secured in the stationary tank.

The ore which is to be treated is placed in the drum or anode compartment with a sodium-chloride solution, and is agitated by the anodes as the drum rotates, the metal being dissolved by the liberated chlorine. It is stated that the dissolved metal is not deposited from the cathode.

300,951, June 24, 1884, Henry Benner Cassel, of New York, N. Y.

Gold. Pyritic and other refractory auriferous ores are electrically dissolved in a sodium-chloride solution. Lime, or equivalent, is added to neutralize the hydrochloric and hypochlorous acids formed and prevent their converting iron in the ore into a proto-salt which would precipitate the gold from its chloride solution.

Or a solution may be employed which will yield a base capable of neutralizing the acids.

317,245, May 5, 1885, Edward P. Thompson, of Elizabeth, N. J., assignor of three-fourths to E. P. Roberts and G. H. Pierce, both of Cheyenne, Wyom.

Gold. Dissolves gold by placing the ore in a tank of lead lined with paraffine, pitch or asphaltum, filled with water and introducing a stream of chlorine at the bottom. The resulting gold-chloride solution is electrolyzed in a cell having anodes and cathode of carbon. Some gold ore may also be placed in this cell to absorb the chlorine freed therein. A number of cathodes coated with gold are packed with fine charcoal in a crucible and heated until the gold melts and runs into a button at the bottom. The chlorine for treating the ore may be produced in an electrolytic cell having an anode of carbon and a cathode consisting of a metal pipe through which steam is introduced into the solution of sodium chloride, acidulated with a few drops of hydrochloric acid. Or a lead-chloride solution may be electrolyzed between a carbon anode and a lead-plate cathode.

BOOK REVIEWS.

Electrische Öfen in der Eisenindustrie. By Dipl-Ing. **W. Rodenhauser** und Betriebsdirektor **I. Schoenawa.** Octavo, 326 pages, 127 illustrations. Price in paper, marks 13.50; cloth, marks 15. (Retail price in New York: $4.50.) Leipzig, 1911; Oscar Leiner.

Electric furnace literature contains many erroneous statements and claims, which contradict the fundamental principles of electrotechnology. The authors have placed before themselves the task of giving complete and accurate information on the electric furnaces used in the iron and steel industry and their operations.

It is not probable that there are in Europe many more metallurgical engineers better qualified to accomplish this task than the designer of the Roechling-Rodenhauser induction furnace and his chief works manager, the above named authors. That two such busy technologists would take the time to write such a treatise for the benefit of the industry and the enlightenment of their colleagues and competitors proves that they are the opposite to narrow technicians—proves that they are broad-minded benefactors of science and industry.

Congratulations are due them in the successful manner in which they have executed their task. To those interested in electric furnaces it may seem that the authors have exaggerated the relative advantages of the induction furnace; but a sober second thought on this question will suggest the possibility that induction furnaces are perhaps better suited for certain metallurgical operations than electrode furnaces, and that their star may be again in the ascendant.

Herstellung Kolloider Lösungen anorganischer Stoffe. Ein Hand und Hilfsbuch für die Chemie und Industrie der Kolloide. von Dr. **The Svedberg**, Privatdozent an der Universität Upsala. Octavo, 507 pages, 60 illus. Dresden: Theodor Steinkopff.

Kapillarchemie. Eine Darstellung der Chemie der Kolloide und verwandter Gebiete. von Dr. **Herbert Freundlich**, Privatdozent un der Universität Leipzig. Octova, 591 pages, 75 illus. Price, 17.50 marks. Leipzig: Akademische Verlagsgesellschaft m.B.H.

These books represent one of the most rapidly advancing branches of theoretical and applied chemistry; a field practically on the border line between physics and chemistry. The extent to which colloidal chemistry has been proved to enter into the chemistry of every-day life and the vast field opened up for experiment, observation and development of satisfactory theory should, and undoubtedly will, attract many earnest chemical students. Dr. Svedberg's book deals principally with the processes of producing colloids by the methods of condensation and of dispersion, while Dr. Freundlich's deals principally with surface tension, separating surfaces and the detailed properties of suspension colloids, emulsion colloids and gels. There is a wealth of interesting and useful information in these two works.

New York Meeting of the American Electrochemical Society.

New York, as a convention city, is a somewhat dangerous place, as experience has shown that while it is easy to get a good attendance on paper in form of a long registry list, yet it is difficult to hold the members together for any length of time. No such difficulty was experienced at the recent convention of the American Electrochemical Society and this fact is conclusive evidence that those who attended it came with a purpose and that the society at its meetings gives to its members what they want and need. It was interesting to analyze the personnel of the attendance. There were those typical electrochemists—many of them from Niagara—who have attended practically every meeting of the Society from the beginning. But the nucleus has grown. The new recruits have come both from the chemical and metallurgical fields. Pittsburgh alone, for instance, has sent large and enthusiastic delegations to every one of the last meetings. The circle is larger, but the esprit de corps is the same as in olden times. The growth of the Society reflects accurately the growth of the industry.

Simple Tin Reduction.

In searching the rather meager literature on the metallurgy of tin one is struck by the lack of definite information which would enable a metallurgist ordinarily skilled in his profession to undertake the reduction of tin ore with reasonable prospect of success. In a general way it is understood that both shaft and reverberatory furnaces have been used, but regarding the details of smelting mixtures and compositions of slags contributors generally are silent. Two queries arise in this connection. Is it to be inferred that the reduction of tin is a complex metallurgical process evolved by the highest technical skill and hence held as a trade secret? Or are the conditions of success so variable according to local conditions that the principles of the process are not reducible to terms for general guidance? Perhaps the truth lies partly in the answer to both questions.

Undoubtedly the impurity of some tin ores, contaminated as they are with bismuth, tungsten, arsenic, iron, copper and zinc, has been responsible for the seeming complexity of their treatment. Roasting, leaching and concentrating are preliminary processes in many instances; and the smelting and resmelting of slags, liquating and poling of the reduced tin, and retreatment of impure residues, comprise accessory processes which give an aspect of complexity to the work. Finally, the production of grades of tin of varying purity testifies to the difficulty of securing a uniformly pure product.

It is rather refreshing, therefore, to find that the recent reduction of tin ore in Texas is characterized by simplicity which is in striking contrast to the complex procedure mentioned. True, natural conditions are favorable in that the

cassiterite is quite pure; nevertheless, those in charge of the work were obliged to put their own ideas into practice, despite the predictions of failure from foreign sources. Their success was striking. By mixing the fine tin concentrate with 8 per cent to 12 per cent fine anthracite coal, heating and rabbling the mixture on the hearth of an oil-burning reverberatory furnace, the tin was reduced in a pure condition, 99.8 per cent and 99.9 per cent fine, ready for market. No slag-forming ingredients were added, and no slag made; nor was it necessary subsequent to refine the tin by liquation or by poling with green wood. Later we shall have more detailed information to present regarding this interesting work.

The Pachuca Agitator.

A note of striking unanimity was sounded by all cyanide experts in their annual reviews for 1910 in regard to the use of the Brown or Pachuca tank for agitation. Almost with one accord they hailed it as the best machine for agitating ore pulp in cyanide solution, and recorded its triumphant path through the goldfields of the world. Apparently the only objection which had been raised to the Pachuca tank, viz., its height and the consequent head-room required, was regarded as having been removed by the system of continuous treatment adopted by Grothe and Kuryla. And yet if the literature be searched for information regarding the agitator little will be found except the usual description embodying dimensions, time required and results obtained. All of which suggests that perhaps the Pachuca tank has been accepted at sight, without being subjected to the exhaustive inquiry usually directed toward kindred devices.

It is not surprising, therefore, that recently some investigations have been made regarding the height of the tank, and whether such height is necessary to accomplish to best advantage the primary purpose of the machine, viz., solution of the precious metals. In ordinary practice the central air-lift extends practically the full height of the tank, and pulp and air are discharged at the top, the former settling for further agitation and the latter escaping into the air. The question arises whether, considering the great height of the tank, 45 ft., it offers the fullest opportunity for dissolution of the values throughout the cycle of operations. Aeration is probably effective only in the central column, and at the top of the charge, while dissolution may not be effective in the return downward path of the pulp.

Several experiments apparently have proved that the air-lift should discharge considerably below the surface of the charge in order that better aeration and dissolution may occur. Philip Argall has modified standard practice at Cripple Creek by shortening the central pipe so that the pulp is discharged 8 or 10 in. below the surface of the charge, thus spreading the air through the upper portion of the charge, and improving aeration and dissolution. A. J. Yaeger has gone further. At the Zambona Development Company, Mexico, the tank has been modified until now the central air-lift is but half the height of the tank, and the discharging air rises in small bubbles through the upper half of the charge, materially improving agitation and increasing extraction as compared with former practice.

As stated above, the main object of the tank is to secure solution of one or two of the elements in the mixture. The physical conditions governing rapid solution require that fresh surfaces of the substance to be dissolved be continuously exposed to the solvent, either by changing the position of the substance in the solvent, or allowing the latter to flow over it, or both. A. W. Warwick has suggested that these conditions are not fulfilled in the great mass of pulp falling in the tank outside the central air-lift, and that the machine is consequently inefficient, considering its great height and volume. Granting that agitation and aeration occur in the central air-lift and at the surface of the charge, may it not be probable that on settling the particles of ore and the solution fall at too nearly the same rate of speed to provide the best conditions for solution.

The Pachuca tank is unquestionably a success, but perhaps the chemist has accepted the dictum of the mechanical engineer without due inquiry, and we may look for material improvement as the former makes more thorough investigation.

Steel Production in 1910.

Official statistics show the production of steel ingots and castings in the United States in 1910 to have been as follows, in gross tons:

Bessemer (acid)	9,412,772
Basic open-hearth	15,292,329
Acid open-hearth	1,212,180
Total open-hearth	16,504,509
Crucible	122,303
Electric	52,141
Miscellaneous	3,194
Total, all steel	26,094,919

There is a gain in the total over 1909 of 2,139,898 tons and of 2,700,000 tons over 1906 and 1907, the two best previous years, 1909 having been an "off" year with an output of only 14,023,247 tons.

The total in 1910 comprised 940,832 tons of castings and 25,154,087 tons of ingots. Statistics of rolled steel in 1910 will hardly be completed until late in the year. In 1906, 1907 and 1909 the rolled steel was about 22.5 per cent less than the tonnage of ingots, this representing in small part the unavoidable losses of material, but in large part scrap produced in rolling and which was promptly returned to the Bessemer vessel or open-hearth furnace, chiefly the latter, to be remelted, the same steel thus passing again over the ingot scales. What is customarily given as the "production of steel" is really the record of the ingot scales. The production of steel is more properly the production of rolled steel, weighed after its last hot rolling and after it has been cropped. Applying the 22.5 per cent just derived the production of rolled steel in 1910 promises to be about 19,600,000 tons. We may anticipate a little by observing that in 1909 the production of rolled iron amounted to 1,709,431 tons, so that the total production of rolled iron and steel in 1910 promises to be in the neighborhood of 21,00,000, or 21,500,000 gross tons. In addition we have the 940,832 tons of steel castings, while the iron foundries probably produced not far from 10,000,000 tons of iron castings. The total doubtless exceeds 30,000,000 tons, comparing with 27,298,545 tons of pig iron produced in the year. There is, of course, a large utilization of scrap, by steel works, iron

mills and foundries. A small part of the rolled steel is old material rerolled, the chief products being light rails, bedstead angles and concrete reinforcing bars.

The basic open-hearth steel industry has taken chief rank in our steel processes so suddenly that there is little to say from a statistical standpoint. In 1907 the total open-hearth steel production fell just short of the Bessemer, with 1,270,421 tons of the open-hearth steel made by the acid process; in 1908 the basic open-hearth steel alone exceeded the Bessemer output, but both processes fell far short of equalling their previous records; in 1909 basic open-hearth steel showed a much larger tonnage than Bessemer and acid open-hearth combined, these being the two processes which use pig iron and scrap of limited phosphorus content. In 1910 the production by the basic open-hearth process exceeded that of the Bessemer process by 62 per cent. There is no prospect of the Bessemer process ever equalling its record output, made with 12,275,830 tons in 1906. Since that year no new Bessemer plants have been built, while one efficient plant has been dismantled and another has been turned largely to the practice of the duplex process. How far the electric refining furnace as an accessory to the converter will be able to change the situation it is too early yet to surmise. That the electric furnace will become of decisive importance, however, in this respect, there can be no doubt.

Efficiency and Conservation.

Much has been written of late in both technical and popular magazines on the subject of efficiency and scientific management. It is a rather remarkable fact that although the principles of efficiency engineering are scientific in the highest degree, yet their application has been largely in the field of industry rather than of science. The tradesman, mechanic and factory hand have been its beneficiaries, while the strictly scientific worker has either been purposely neglected or considered able to direct his own efforts to attain the highest degree of efficiency. There may be a subtle compliment in this neglect of the scientist, and if so, fact and conditions ought to show him worthy of it, but we suspect that investigation will find him a transgressor in many simple and almost inexcusable ways.

Efficiency implies system; system implies knowledge of details, and this, in turn, implies brains. We thus come to brains, or a central competent head, as the foremost requirement of efficient work in a laboratory, smelter or plant. Next in point of importance comes the individual ability of the man for his task, and the collective efficiency of the entire corps of men engaged in work to a common end. Finally, the correct design of the plant, the construction of the various buildings, and means for accomplishing the necessary work, form a vital element in the whole system of efficient operation. Given these conditions we have operative conservation in its truest form, as far as it relates to time, money, material and energy.

The directing head of a chemical or metallurgical plant should have more knowledge of the work in hand than any of those under him. This may seem a self-evident proposition, but the instances have been known, especially in the early history of metallurgy in the West, where the smelter boss and the political boss were one and the same, and where technical positions were granted for some real or fancied service in another sphere of activity. Under such conditions metallurgical efficiency and conservation were at a low ebb, and financial success ensued only because the property could stand mismanagement. Those in charge were incompetent to initiate improvements, or pass competently on the suggestions of their employees, many of whom were far superior in technical skill and ability, but without authority to enforce their views.

On the second point—individual fitness and the collective ability of the entire corps—an inquiry often will reveal weak points which do not appear on the surface. We can recall cases where excellent laboratory chemists apparently failed when placed outside, and again where men seemingly poorly adapted to the work of the laboratory made successes in the plant. It is the old problem of the square peg and the round hole, and presents a condition where both individual efficiency and the general efficiency of the plant would be higher if the men were kept where they could work best. The routine work of the laboratory, made up as it is of a few separate operations, each repeated many times during the day, requires a certain temperament for its best performance, and the man who can do it well may not be able to direct those larger operations in the plant which consist in the handling of labor and material, and the economical output of the product.

On the third score, viz., correct design and construction of plant, we find many transgressions of the laws of efficiency and conservation. Perhaps nothing has been so potent in the development of chemical and metallurgical engineering as a profession as the mere fact that those on whom the chemist or metallurgist formerly relied for design and construction of plants, did not fully understand the technical requirements of the plant as a whole, and hence failed to produce the best result. The chemical and metallurgical engineer was a logical development in the demand for efficiency in plant construction. The design and construction of a plant, of the individual buildings, and their grouping together, all exert a wonderful influence on general efficiency. Poor arrangement will nullify the benefits gained through a trained corps of workmen, and illogical design will defeat the ends of the best appliances. A workman, consciously or unconsciously, will neglect a machine placed in an inconvenient place. He will not inspect those parts of the plant which are difficult of access, or which are uncomfortable to visit, with the same regularity or willingness that he will perform the more agreeable part of his duties. Hence the necessity for construction and arrangement which, per se, will not constitute a cause for neglect of duty.

Poor arrangement of laboratory or plant will cause many unnecessary steps to be taken and useless time consumed in transporting material from one part to another. The cost of these wastes of time and energy will amount to a considerable sum per annum, and frequently they will not be appreciated until an investigation has shown where loss can be changed to profit. Fortunately, as said before, the chemical and metallurgical engineer is taking care of these matters as never before in the history of the industry. Much is required of him. He must have mental ability and physical capacity; executive as well as engineering training, and business sense of a high order. With these qualities he will not be guilty of making avoidable wastes and recoverable losses, and will give high efficiency and genuine conservation in all his work.

Notes on Chemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

Electric Furnaces and Heating.

In the course of the second Cantor Lecture, recently delivered before the Society of Arts, Dr. J. A. Fleming said that the methods of electric heating were classified into resistance heating, arc heating and combinations of the two. He mentionad Sir William Siemens' early experiments on the electrical fusion of steel in 1879, and described the electric-arc furnaces of E. Stassano and Paul Héroult in 1898 and 1899. Héroult in 1900 manufactured steel from pig iron and scrap by means of his arc-resistance furnace; and furnaces were at La Praz now producing six or more tons of steel a day, at an expenditure of 800 to 900 kw-hours per ton. Pig iron could be prepared electrically from hematite by an expenditure of about 2,000 to 2,200 kw-hours per metric ton. The modern blast furnace used only about 16 cwt. of coke per ton of pig, of which 6.5 were required to reduce the ore, and the cost of electric energy must be reduced to 0.1 cent per kw-hour before the electric smelting could compete with the blast furnace. Electric furnaces, however, worked efficiently in the production of high-grade steel from scrap iron and pig in the place of, or as supplementing, the open-hearth process. The Girod arc furnace as developed by M. Paul Girod and used at his works at Ugines produced a high-class steel from scrap iron by an expenditure of 1,000 to 1,100 kw-hours per metric ton. The danger of carbon contamination by the arc furnace electrodes led to the invention of the Ferranti induction furnace, in which a large alternating-current transformer had a secondary circuit consisting of an endless channel lined with magnesite or dolomite, in which the metal was melted by induced currents. The Kjellin furnaces at Gysinge produced excellent steel from pig iron and scrap, consuming about 900 kw-hours per ton of steel; electric energy costing about 0.09d per kw-hour, or £2 per electrical hp-year. In combination furnaces, in addition to the heating of the charge by the induced currents, current induced in a copper secondary circuit was led through the charge from metal electrodes embedded in the furnace lining. The power factor was raised and the combination furnace could be worked at a higher frequency and by three-phase currents. Moreover, this furnace had a roomy and accessible hearth, and was excellent for refining. By using a basic lining sulphur and phosphorus could be eliminated and the occluded gases entirely removed, while the metal was not oxidized as in open-hearth furnaces. Another advantage was the economy of labor compared with the ordinary crucible processes. The electric furnace produced a high class of steel equal to the best crucible steel, and was especially adapted to the production of alloy steels, viz., vanadium, chrome and tungsten steels.

A 10,000-Volt Battery.

Mr. A. A. Campbell Swinton, at a meeting of the Röntgen Society, described a battery consisting of 4800 cells, a number which divided up into convenient sections of 80 cells for charging in parallel off a 200-volt supply. Arranged in series, it gave 10,400 volts on open circuit. Each cell consisted of a glass test tube 4 in. long and ¾ in. bore, and each set of 40 cells was cast solid with paraffin wax into a wooden tray. The battery was of the Planté type, and the plates were made of sheet lead cut into strips which were bent round a shaped piece of wood and pressed to a corrugated form not very liable to deformation. The plates were kept from touching each other by celluloid separators, and were all formed in a nursery battery before being transferred to the battery proper. The total weight of lead in the whole battery was 400 lb., and the total weight of the whole of the battery, exclusive of containing cases, was nearly 1000 lb.

To avoid bubbling the battery was charged at a rate not exceeding 10 milliamperes, and it was capable of discharging at a rate of 150 milliamperes, giving 1½ kw for several minutes. The internal resistance varied between 3000 and 4000 ohms.

With 10,000 volts between polished brass balls 12.5 mm in diameter the current was found to jump 2.5 mm, and the arc could be drawn out to a considerable length, dependent on the resistance in the circuit. That the current was often not entirely continuous was indicated by the arc making a whistling sound. A Leyden jar connected across the arc immediately converted it into a series of discontinuous sparks which, if the jar was of small capacity, followed one another very rapidly, producing a musical note which deepened into a roar when the capacity was increased. The battery showed very plainly the electro-capillary effect discovered by the late Lord Armstrong. At 8000 to 10,000 volts and about 5 milliamperes, and using pure water, the results were exactly similar to those obtained by him with hydroelectric and induction-coil discharges. The addition of a very small quantity of dilute sulphuric acid to the water, which destroyed all movement of the thread when induction-coil discharges were employed, was found, with the battery current, not entirely to stop the thread moving, but increased the flow of water in the opposite direction. Practically all the Crookes and other vacuum-tube effects could be obtained with the battery current.

Rusting of Steel in Concrete.

The draft report of the science standing committee on the "Rusting of Steel Inside a Concrete Covering," which was presented at a recent meeting of the Concrete Institute, stated that a circular was issued in 1909 by the Concrete Institute asking for observations on the question whether rusting of steel takes place when covered by concrete, and was sent to 1000 engineers and others engaged in concrete construction.

Only 111 replies were received. Forty-seven contained results of definite observations, in which 26 cases of rusting had come under notice, and in 43 cases no rusting had been found.

As a result of these investigations the committee has arrived at the following conclusions: Reinforced concrete is as durable as plain concrete in any situation provided that certain precautions are taken in construction.

The cement, sand, stone, etc., must be of good quality, and must be carefully and thoroughly mixed and scientifically proportioned, so as to be practically waterproof and airproof. The mixture must be fairly wet and must be well punned into position to minimize voids. The aggregate should be as nonporous as possible, and no aggregate known to have a chemical action on steel should be used. The aggregate should all pass through a ¾-in. mesh. The concrete covering should never be less than ½ in., and with round or square bars the covering should not be less than the diameter of the bar. In structures exposed to the action of water or damp air the thickness of covering should be increased at least 50 per cent, or the size of the aggregate should be reduced so as to ensure a dense skin. Structures exposed to very severe conditions should have the concrete covered with some impervious coating.

The reinforcement should allow sufficient space between one piece and its neighbor for the concrete to pass and to completely surround every part of the steel. All steel should be firmly supported during the ramming of the concrete to avoid displacement. It should not be oiled or painted, and thick rust should be scraped and brushed off before placing in position.

The scantling of the various members of the structure should be sufficient to prevent excessive deflection. If electric mains are laid down care must be taken that no current is allowed to pass through the reinforced concrete. Fresh water should be used in mixing, and aggregates charged with salt should be well washed.

Engineering Imports and Exports.

The Board of Trade returns for January and February show that the imports of iron and steel, including manufactures, amounted to £1,689,512, or £328,048 more than during the

corresponding period of last year; and the exports were £7,196,410, showing an increase of £609,054. The imports of other metals and manufactures thereof were £4,318,634, and the exports £1,708,186, a decrease of £83,083 in imports and an increase of £96,000 in exports. The imports of electrical goods last month were £231,549, an increase of £9,567, and exports reached £428,724, giving an increase of £75,880. The imports of machinery are valued at £884,912, an increase of £235,957, and the exports at £4,714,446, an increase of £693,878. Imports of new ships were £37,092, an increase of £36,690; exports amounted to £620,847, a decrease of £1,665,134.

Market Prices.

March, 1911.

Copper has not varied much this month. Opening at £54.13.9 it reached £55.1.3 by the 15th, afterward easing off to £54.17.6, and is now (29th) at £54.15.0.

Tin has been over a 10-pound range, but rather less jerkily than before. Starting at £189.10.0 it had dropped by the 15th to £178.10.0, afterward recovering to £182 and now quoted £185.17.6.

Lead has been depressed, dropping from £13.12.6 to £13.10.0 by the 15th and ultimately to £13.5.0.

Hæmatite has also fallen. Opening at 66/2 it was 65/- at midmonth and now shows 64/3.

Pig Iron (*Scotch*) has dropped similarly from 54/9 to 54/4½ and then to 53/7½.

Cleveland Warrants opened at 48/8½ and dropped steadily to 48/3 (15th) thence to 47/7½.

India rubber has been cheaper, falling from 7/1, the opening price, to 6/10 by the 8th and 6/6½ by the 15th; was 6/7½ on the 22d and 5/11½ on the 29th, closing at 5/9½.

Alum, lump, loose, per ton	£5.12. 6.
Antimony, black sulphide powder	22. 0. 0.
Borax, British refined crystal	16. 0. 0.
Sulphate of ammonia, f. o. b. Liverpool, per ton	14. 7. 6.
Sal-ammoniac, lump, firsts, delivered U. K., per ton	42. 0. 0.
Copper sulphate, per ton	19.17. 6.
Camphor, 1-oz. tablets	0. 1.10.
Caustic soda, ash, 48 per cent ordinary, per ton	5.10. 0.
Shellac, standard T. N. Orange spots, per cwt	3.13. 0.
Sulphur, recovered, per ton	5. 0. 0.
Carbolic acid, liquid, 97/99 per cent, per gal	0. 1. 5.
Hydrochloric acid, per cwt	0. 5. 0.
Creosote, ordinary good liquid, per gal	0. 0. 2.
Naphtha, solvent, 90 per cent at 160° C., per gal	0. 0. 9.
Petroleum, Russian, spot, per gal	0. 0. 5.
Copper ore, 10 to 25 per cent unit	9/1½ to 9. 7.
Tin ore, 70 per cent, per ton	£112 to 114.0. 0.
Mica, small slab, in original cases, per lb	6d. to 1. 0.
Litharge, flake, per ton	15.10. 0.
Quicksilver, per bottle, Spanish, 75 lb	£9.7.6 to 12. 0. 0.
Zinc sheets, V. M., f. o. b. Antwerp	27.10. 0.
Red lead, genuine, per ton	16. 0. 0.
Bleaching powder, 35 per cent, per ton	4. 5. 0.
Platinum, per ounce, nominal	8. 6. 6.

On the month the following differences are noted:

Lower.	Amount.
Hæmatite	£0. 2. 0.
Pig Iron (Scotch)	0. 1. 7.
Cleveland Warrants	0. 1. 3½.
Tin ore	11. 0. 0.
India rubber, para	0. 1. 3½.
Tin	3.12. 6.
Lead	0. 7. 6.
Higher.	
Sulphate of ammonia	0. 5. 0.
Shellac, T. N. Orange spot	0. 1. 0.
Carbolic acid	0. 0. 1.
Copper, per ton	0. 1. 3.

The Congress of Technology in Boston.

The Congress of Technology which met in Boston on April 10 and 11 in celebration of the semi-centennial of the signing of the charter of the Massachusetts Institute of Technology was a pronounced success.

The opening session of the Congress was begun with an address by President Maclaurin of the Institute, who spoke on "Some Factors in the Institute's Success," and attributed that success primarily to the method of instruction, now everywhere accepted, but not long ago a debated venture.

"Apart from his appreciation of the value of all sound learning," said Dr. Maclaurin, "Wm. Barton Rogers, the founder and first president of the Institute, saw clearly that the whole controversy as to the relative merits of science and the classics in the field of education missed the mark by placing the emphasis in the wrong place. He understood that when one gets to the root of things in education, the *method* rather than the *subject* is of supreme importance, and his insistence on the value of method in teaching was the cardinal doctrine in his creed and the one that has contributed most to the success of the Institute. His fundamental idea here was not original with Rogers. It has been clearly expressed before, but rarely, if ever, adopted definitely as the basis of educational method and applied systematically throughout. The idea is familiar to us all to-day, the idea of *learning by doing.*"

The daylight hours of the second day were given over to the presentation of papers on various aspects of applied science. These papers were grouped in six divisions, and the times of reading were so arranged that the general public, a large number of whom had received personal invitations, were enabled to hear papers in several divisions on topics in which they were particularly interested.

The result of these sessions amply justified the plan. Every session was very largely attended, and as the papers dealt not with educational or technical abstractions but were on the contrary striking and vital reports from the actual field of industrial work, the large audiences gained a better conception than would otherwise have been possible of the fashion in which applied science has remade the life and habits of the world within the last half century. Some of these papers are printed elsewhere in this issue.

The other main object of the Congress was achieved with equal certainty. The papers were all given by Technology Alumni and members of the faculty and the great range of accomplishment which the papers reported were a splendid certificate of merit and efficiency running to the credit of the men trained at the Institute.

Another feature that is perhaps of more importance than either of the two already mentioned is that the Congress has set clearly before the public the needs and the possibilities of what the speakers on Tuesday evening called the "New Technology." The high standard of the Massachusetts Institute of Technology, and its well deserved fame as one of the very foremost technical schools in the world, hardly need reiteration. But the very success of the Institute has brought it to a point where insufficient endowment and cramped quarters threaten seriously to interfere with its future usefulness unless the obstacles are very soon removed.

The banquet in Symphony Hall on Tuesday evening, April 11, provided a significant sign of deep appreciation of this need both by the alumni of the Institute and by many others outside of its immediate ranks. The enthusiasm of the thousand alumni and guests who filled the floor of the hall was reflected in the words of the speakers, who included two such notable figures in Institute affairs as President Lowell of Harvard, long a member of the Corporation of Technology, and President Emeritus Eliot of Harvard, who was professor of chemistry in the original Institute faculty.

The temper of this great meeting was significant in showing a sharp consciousness of a new era created by applied science;

of the important part that has already been taken by graduates of the Massachusetts Institute, and of the pressing need, especially from the point of view of the interest of Massachusetts, that the Institute should be immediately equipped with the additional means for enabling it to continue in the future as it has been in the past, a leader in technical education.

The practical earnestness of the alumni in doing their full share toward making possible the "New Technology" was shown in three announcements made by President Maclaurin from the platform after the banquet. One alumnus, who wished his name withhheld, has offered to the Institute a tract of 1000 acres of land in Maine, well suited to the uses of a summer school in civil engineering. Other alumni have definitely pledged themselves to give a very large part of the price necessary for buying a new site for the Institute. Edward N. Hagar, Tech '93, president of the Universal Portland Cement Company, has promised as a gift all the cement needed for erecting the new buildings in reinforced concrete. Meanwhile, the question of the site itself, Dr. Maclaurin said, has been narrowed to a choice between three sites, all of which are within a short distance of the present buildings. It is expected that this question of a new site, upon which everything else in the development of the Institute depends, will very soon be settled.

The Western Metallurgical Field

Dredging in South Dakota.

A Denver corporation known as the Castle Creek Hydraulic Gold Mining Company is preparing to carry on dredging operations on Castle Creek, near Mystic, S. D., this summer. About 700 acres of ground were acquired by the company, most of which is amenable to dredging, and over 100 acres of which have been proved by bore holes. The average value of this ground was proved to be $1.30 per yard, most of the gold being coarse and easily recovered. It is estimated that the cost of dredging will be very low, possibly as low as 5 cents per yard, as the ground contains no large boulders and there are no unusual obstacles to be overcome.

The dredge, which is now being built, will be in operation this summer. It is of the type which has proved so successful in California, with 5-cu. ft. buckets, and a hull measuring about 100 ft. x 36 ft. at water line. It will be operated by electricity generated at the company's power plant, which comprises four 100-hp boilers, a 300-hp Corliss engine and generator. The power requirement under full load is estimated to be 240 hp.

Winter operation is to be made possible by a suitable steam heating plant, with an inclosure over the stacker. The depth to bedrock is about 35 ft., which gives a large yardage on the area already proved. If the first year's operations prove successful it is possible that another dredge will be built to work on the other end of the tract. Assays on the fineness of the gold have given results of 947.5 fine.

Copper Concentration.

The work of the Utah Copper Company in concentrating large quantities of low-grade copper ore is generally conceded to be in the front rank of concentration. The report comes from Butte that representatives of the Anaconda Copper Company have been investigating the methods of the Utah company, with a view to making some changes in the Montana mills. The devices particularly attracting attention are the Garfield roughing table and the Janney classifier, the latter being an invention of the mill superintendent of the Utah Copper Company.

The roughing table has proved its value in preparing a lean pulp for treatment on standard tables by getting rid of a large quantity of gangue, thus practically making an enriched ore for the regular tables. The Janney classifier has been an improvement in the treatment of fine pulps, and is used in both the Utah mills.

At Anaconda jigging is the main treatment and is carried to a fine point, the smallest jig concentrate being 1 mm in size. Following this are the Wilfley tables, but a large quantity of slime escapes treatment and is impounded. There are no vanners in the Anaconda plant, while in the Utah plants the vanner is relied on for a large percentage of the recovery. It is said that experiments will be made at Anaconda to test the value of the roughing table between the jigs and Wilfley tables, and that Janney classifiers and vanners will be tried on the finer sizes not treated on the Wilfley tables.

The Nevada Consolidated also is reported to contemplate experiments with various slime tables for the purpose of reducing the present slime losses, which are high on this ore. In the smelting department of the same company alterations are being made to test the basic lined converter. Should this method of converting prove successful, and it probably will be as successful there as at Utah, the old battery of acid-lined converters will be displaced by those of the new type.

Macquisten Tubes in Idaho.

Of the various flotation processes which have been proposed or operated, the Macquisten tube is one of the most interesting. The more common floation processes make use of oil or acid, or both, to make the mineral particle buoyant, but the Macquisten process makes use of a different principle, viz., the varying action of mineral and gangue particles to the surface tension of water. Sulphide minerals are apparently unable to overcome the surface tension of water when delivered onto its surface, and, therefore, float, while gangue particles promptly sink. Thus for sulphide mineral particles, gravity is a lesser force than the surface tension of water.

The Macquisten tube is a cast-iron tube about 6 ft. long and 1 ft. in diameter. On its inner surface it has a helical groove and on its outer surface two tires which rest on supports. It is revolved in a horizontal position, and the ground pulp is delivered at one end. Being revolved in the direction of the helical groove in the interior, the pulp is screwed through the tube to the discharge end. Naturally in the revolutions of the tube the pulp in any groove is raised out of the water, which is maintained at a definite height in the tube, and on sliding down the side of the tube the mineral particles tend to float while the gangue sinks and is carried to the next groove. This separation depends somewhat on the angle of emergence of the pulp from the water, as the greatest floating effect is obtained when the mineral is directed onto the surface of the water at a small angle.

The latest important installation of this process is in the Morning mill of the Federal Mining & Smelting Company, Wallace, Idaho. Its object will be the treatment of low-grade zinc middlings. The first unit will be of 50 tons capacity and will use about 120 tubes. If this proves successful, additional tubes will be added to give a capacity of 250 tons per day. The plant should be in operation in May or June.

Cyanide Tailings Treatment.

Another interesting plant which will be in operation about the same time as the one just mentioned is that of the United States Reduction & Refining Company, at Florence, Col. At this place are the large tailings dumps of the old Union plant and the Metallic Extraction Company. There are upward of 300,000 tons of material in each dump, representing the tailings from the early application of the cyanide process on Cripple Creek ores.

The success which the company has met with in cyaniding old tailings at the Standard plant at Colorado City has led to the erection of the present plant at Florence. About 400 tons of tailings will be treated daily at the new plant, and a good net profit is anticipated.

There has been some talk about starting the smelter owned by this company at Canon City. This plant formerly treated zinc ores and produced pigment, but it has not been operated for several years. Several proposals have been made by prospective

leasers to again operate it on zinc ores, but no definite results have transpired. Experiments also have been made by outsiders on the old dump of the smelter to see whether a profitable extraction of zinc could be made from it, but for some reason or other no further action was taken.

Tungsten from Nevada.

The first shipment of tungsten concentrates from White Pine County, Nevada, was made in March by the United States Tungsten Corporation. The mill is operated by water-power when water is plentiful and by an auxiliary steam plant at other seasons. The latter plant is inadequate for the needs of the mill, and consequently operations have been on a small scale during the winter. It is expected that this summer's work will result in a steadier output.

The grade of the concentrate is up to the standard of 60 per cent tungstic acid.

Mason Valley Smelter.

The construction of this plant in the Mason district, Nevada, is progressing rapidly and satisfactorily. Some time ago the contracts were let for the electric equipment, and more recently the bid of the American Bridge Company for the structural steel work was accepted. The contract calls for 400 tons of structural steel at a cost of about $40,000. This provides for the construction of blast furnace and converter building, sampling mill, power house and ore bins. The initial capacity of this custom copper smelter will be 800 tons per day, but this can be increased easily to 2000 tons on demand.

American Mining Congress.

The fourteenth annual session of the American Mining Congress will be held in Chicago, Oct. 23-28, 1911. This probably will be the last session of the congress at which the present delegate system will prevail. At present delegates to the congress may be appointed by the president, governors, scientific societies, etc., but in the future it is planned to have a congress of members only, and to have this congress represent the different sections of the United States. The reorganization scheme also includes the establishment of State chapters to carry on the particular work of the State and to send delegates to the annual congress. In this way the congress will not be so unwieldy and cumbersome as it is now, and better work can be done than before.

The Non-Ferrous Metal Market.

The non-ferrous metals were without feature on the market during April. Copper has tended to decline, as has spelter, but lead has showed a slight spring improvement. Purchases seem to be only for immediate needs.

Copper.—The market has been marked by dullness, and large business has been consummated only at some concession in price. Lake copper is quoted lower than in our last report, being 12¼ to 12⅜ cents. Electrolytic is quoted at 11.95 to 12.05 cents.

Lead.—The April market showed an advance over March, and this improvement seems to hold. St. Louis lead is quoted at 4.25 to 4.27½ cents, and New York, 4.40 to 4.42½ cents. The demand for Missouri lead has shown improvement during the month.

Spelter.—Although reports are to the effect that consumers are not well supplied, the business in spelter is quiet. Prices have shown a tendency to decline from day to day, and the market is generally lower than in March. St. Louis spelter is quoted at 5.22 to 5.27, and New York, 5.37 to 5.42.

Tin.—Transactions abroad indicate that the foreign syndicate dominates that market, but developments in the domestic market during the month showed that the influence of the London market was not strong here. April tin showed a steady increase in price as compared with March, and was quoted at 42⅛ cents, New York.

The Iron and Steel Market.

The event of the month, as regards iron market movements, was the settlement of Lake Superior iron ore prices for the season, at 50 cents below the 1910 schedule, making this season's prices as follows compared with prices in the past 10 years:

	——Old Range——		———Mesabi———	
	Bessemer	Non-Bessemer	Bessemer	Non-Bessemer
1901.....	4.25	2.85	2.75	2.35
1902.....	4.25	3.00	3.00	2.60
1903.....	4.50	3.60	4.00	3.20
1904.....	3.00	2.60	2.75	2.35
1905.....	3.75	3.20	3.50	3.00
1906.....	4.25	3.70	4.00	3.50
1907.....	5.00	4.20	4.75	4.00
1908.....	4.50	3.70	4.25	3.50
1909.....	4.50	3.70	4.25	3.50
1910.....	5.00	4.20	4.75	4.00
1911.....	4.50	3.70	4.25	3.50

Since 1907 the base guarantees have been 55 per cent iron for Bessemer ores and 51.50 per cent iron for non-Bessemer ores, in the natural state, with the phosphorus basis for Bessemer ores .045 per cent, dried at 212°. Prior to 1907 the basis for several years was 56.70 per cent for Bessemer ores and 52.80 per cent for non-Bessemers. Prices are for ore on Lake Erie docks.

The settlement of season prices was unusually late, since the season has nominally commenced, although on account of the light demand there will be relatively little ore moved before July. Occasionally season prices have been fixed before the end of the preceding calendar year. This season found a complicated situation. The advance for the season of 1910 was determined upon late in December, 1909, when the pig iron market had shown dulness and a declining tendency for more than a month. At the moment the condition was regarded as only temporary and the market was expected shortly to resume the steady upward movement which had characterized it from May to the beginning of November. Instead it declined steadily almost throughout 1910, leaving ore prices quite out of line with prices of pig iron, and even of finished steel products. The very badness of the market, however, constituted one argument for maintaining ore prices, inasmuch as merchant furnaces were left in many instances with large stocks of pig iron or ore, or both, upon which a reduction in ore for the new season would necessarily write a depreciation. The steel interests, furthermore, were intent upon preserving the existing level of finished steel prices in face of a very light demand, and decried a reduction in ore on account of the sentimental influence. A meeting of ore interests was held in Cleveland, April 11 and another of ore interests with some of the steel producers in New York, April 18. On Friday morning, April 21, the Shenango Furnace Company, commonly known as the Snyder interest, announced that it had sold two lots aggregating 200,000 tons of Mesabi Bessemer ores and four lots aggregating 550,000 tons of Mesabi non-Bessemer ores, at $4.25 and $3.50 respectively. This informal method of opening the selling season, supplanting the method of a few years ago of holding a meeting of ore interests and then announcing the result of the deliberations, is due to the desire of the ore interests to avoid the appearance of conflict with the later interpretation of the Sherman law of 1890. The ore interests are satisfied to have ore prices for the season on the basis thus indicated.

Total sales of merchant ore for the season are not likely to be heavy, and may even fall short of 5,000,000 tons. In the three years of heaviest movement, 1907, 1909 and 1910, the total ore shipped from the Lake Superior region was between 42,000,000 and 44,000,000 tons, nearly a fourth being merchant ore sold in the open market, the balance being made up of a relatively small tonnage moved on long term contracts, and moved by the producer-consumer class. Various estimates of the

prospective season movement for 1911 range from 25,000,000 to 35,000,000 tons.

April opened with pig iron production at the rate of about 26,000,000 tons a year, there having been practically no change during March, after the sharp increase in January and February. The current production was passing into steel mill, foundry and other consumption, but new orders for finished product were not being booked at a rate to support the production, and new buying decreased until the middle of the month, when the state of the iron and steel market as a whole was one of stagnation. Production began to be curtailed by the middle of the month, the United States Steel Corporation leading, as it firmly follows a policy of regulating its pig iron output to the shipments of finished steel products. Independent steel interests curtailed somewhat more slowly, and probably accumulated some pig iron during the month. The country's production rate at the close of the month was probably well under 25,000,000 tons, while shipments of finished steel products in the second half of the month were at a lower rate than this output would support. There has been little change in production by merchant furnaces, as the demand for merchant pig iron had not grown as brisk early in the year as the demand for finished steel products.

The position at the beginning of May is that buying of finished products is at a much smaller rate than early in the year, and falling quite short of justifying the rate of production, which is declining in consequence. An improvement in buying is to be expected this month, on account of the progress of the season, involving outdoor work and the depletion of stocks due to the extreme timidity of buyers late in March and during April, but it is questionable whether there will be sufficient increase to arrest the decline in production, which has been forced by the deficiency in buying already noted.

Prices of finished steel products are unchanged, and producers do not regard the reduction in ore as cause for any revision. As to both pig iron and finished steel products, the reduction in ore is held to have been discounted long ago by the declines in the more finished products.

Pig Iron.

The market has been extremely quiet, the month's turnover being the lightest for months. Prices have not changed appreciably. Early in the month the premiums demanded for second half delivery began to disappear, the south leading as usual, so that it became possible to buy southern iron for deliveries to the end of the year on the basis of $11, Birmingham. At the same time it appeared probable that for prompt delivery the price could be shaded 25 cents, but this has not been very seriously tested. The reduction in ore prices brought out considerable enquiry for northern iron, but this enquiry seemed to arise purely from a desire to test the market and upon furnaces quoting former prices business did not result. The furnaces insist that the ore reduction was discounted months ago by declines in pig iron, but the matter will ultimately depend upon the competition. The lake front merchant furnaces have a margin above cost which they could if necessary shade, while the Mahoning and Shenango Valley furnaces, whose selling prices have been practically at cost, based on the reduced ore prices, have large stocks, and the competition may force them to accept losses. We quote at valley furnaces, 90 cents higher delivered Pittsburg: Bessemer, $15; basic, $13.75; No. 2 foundry, $14; malleable, $13.75 to $14.

Steel.

Shipments of billets and sheet bars on contracts have decreased somewhat. There has been no new business of importance, but on a few odd lots of open-hearth billets and sheet bars regular prices have been shaded. We continue to quote billets at $23 and sheet bars at $24, f.o.b. maker's mill, Pittsburg or Youngstown, with rods nominally at $29, Pittsburg.

Finished Steel.

The United States Steel Corporation's unfilled orders decreased 3,252,274 tons during 1910, and increased 436,162 tons in January, 289,624 tons in February and 46,758 tons during March, standing at 3,447,301 tons on March 31. A decrease during April is expected to be shown by the report to be made public May 10.

Finished steel products are practically unchanged in price. There has been somewhat more shading in sheets, but the former basis is at least nominally in force. The advance of 5 cents per 100 lb. scheduled for April 1 in spikes became effective in Pittsburg territory, but not in the West, so that the spike market stands at $1.60, Pittsburg, and $1.65, Chicago, base, subject to extras according to the new list adopted February 1 last. Regular price f.o.b. Pittsburg, except where otherwise stated, are as follows:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, 1.40 cents for tank quality.

Shapes, 1.40 cents for beams and channels, 3 in. to 15 in. inclusive, zees and angles, 2 x 3 and larger.

Steel bars, 1.40 cents, base; iron bars, 1.35 cents, Pittsburg; 1.20 to 1.25 cents, Chicago.

Wire nails, $1.80, base, per keg; plain wire, 1.60 cents, base; galvanized barb wire, 2.10 cents; painted barb wire, 1.80 cents.

Black sheets, 28 gage, 2.20 cents; galvanized, 3.20 cents; blue annealed, 10 gage, 1.65 cents; painted corrugated roofing, $1.55 per square; galvanized, $2.75.

Tin plates, 100-pound cokes, $3.70 per box.

CORRESPONDENCE.

Separation of Oxygen by Cold.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Mr. J. J. Smith's letter deals with two points: one theoretical, the other practical. Taking the theoretical first, I have nothing to add to your note at the end of his letter. Mr. Smith has evidently taken Clausius' equations for reversible processes and applied them to irreversible processes. The increase of entropy due to the mixture of two inert gases is not an invention or fallacy of my own; it is quite well known, and Mr. Smith will find it discussed in the works of his own eminent countryman, the late Professor Willard Gibbs.

As to the discrepancy between my figures and those of M. Marchis: the first proofs of my paper had a slip in arithmetic and a few copies were sent out before I corrected it. I merely mixed up watts and kilowatts, a small matter which sometimes gives unexpected results.

At any rate the result astonished and disappointed me until I realized its absurdity and looked for the error. The figure ought to be 120 kilowatts, not 120,000; the prices coming out at about 25 cents a ton. The error justified Mr. Smith in attacking the theory on the ground that the result proved its error.

As this error of mine may have got about I am especially glad of a chance of correcting it.

London, England. James Swinburne.

[The sixth and fifth paragraphs from the end of Mr. Swinburne's paper, that is, the last three lines in the first column and the first nine lines in the second column of page 36 of our January issue, should read as follows, according to the corrected copy of the paper which Mr. Swinburne has kindly sent us:

"Assuming the ideal energy needed to separate a kilogram of air into its gases to be 40,000, the question is: What would it cost in practice? On a large scale it may be safe to say 100,000 joules, or a ton would need 120 kw hours. Taking the cost of a kilowatt hour as low as 0.2 cent, this means 25 cents a ton.

"It certainly looks as if oxygen at this order of figure could be used for blast furnace work. Taking a blast furnace as using four and a half tons of air per ton of iron, to increase the oxygen content by 10 per cent of the oxygen content comes out at 2½ cents per ton of pig. This shows that the Linde process may be useful on a large scale."—Editor.]

Metallography and Its Industrial Importance.*

By Albert Sauveur.

This paper deals with a subject which was not taught at the Massachusetts Institute of Technology during my stay at that institution, which was not even mentioned in the classroom. Indeed, metallography at that time had just been born and had not attracted greater attention than is generally bestowed on infants outside the family circle.

If I have contributed a mite to the growth of the child—to the progress of metallography—why, then, should my Alma Mater be entitled to any credit? Why should I not claim for myself and retain undivided whatever merit be attached to the contribution of my mite?

The reply is obvious. While I did not acquire even the rudiments of metallography in passing through the institute I entered it with an untrained mind and left it with a mind satisfactorily trained for scientific pursuit. This is my greatest debt of gratitude to my Alma Mater. It is why the institute is entitled to the lion's share of the aforesaid credit.

This incident is only a passing illustration of what, to me, is becoming more and more evident as the years go by, namely, that it is not the knowledge acquired at the school or university which is later of vital importance to us, but rather the training of the mind which the acquirement of that knowledge implies. It is this training—this peculiar attitude of the mind—which distinguishes an educated from an uneducated man.

Have not most of us forgotten a large portion of the knowledge obtained at college 10 years after graduation? Do we cease then to be educated men? Are we less educated? Clearly not, for we retain, and possibly have developed further, that mental attitude—that way of looking at things—which distinguishes the educated man.

If this be so does it matter then what we do study while at the university or technical school? While I am not prepared to say that this is immaterial provided we study enough to train our mind, I do not believe that the selection of courses has the importance generally attached to it. I do believe that the educational value of a subject depends more upon its mind training power than upon the specific kind of knowledge which it aims to impart.

Hence the value of mathematics, even for those who never expect to be called upon to perform, after leaving college, more than the four elementary operations. It is, of course, evident that the natural bent of the mind should be followed in the selection of studies—that persons with decided scientific inclination should take up chiefly scientific studies, those with literary taste, classical subjects, etc.—but the value of greater specializing for the purpose of education is, to me, becoming daily more doubtful.

A scientific education should be obtained in four years, during which a sound knowledge of the pure sciences and the rudiments of the most important applied sciences should be acquired, thereby securing the desired mental attitude and scientific way of thinking. If the student then desires to take up as his life's work the application of science in some well-recognized field, such as one of the various engineering professions, his general scientific training should be followed by a course of two years of as practical a character as possible and devoted exclusively to applied science in his chosen field.

During these two years specializing could hardly be carried too far. The student, for instance, should make up his mind not only to specialize in mining and metallurgy, but in mining *or* metallurgy, and in the latter case whether his special training will be in the metallurgy of iron and steel or of the non-ferrous metals. Should he select iron and steel, his two years of post-graduate work should be devoted exclusively to that one subject, or practically so.

In short, for the purpose of education and general fitness to take up a man's burden, let us provide a program of study as broad as possible, avoiding specialization, while for preparation in any one field of applied science let us frankly face the need of specializing; at this stage it could hardly be too excessive.

The prevailing practice is, of course, very different, the young man being made to specialize upon entering college, or possibly upon beginning his second year, and, therefore, at a period when very few can make an intelligent choice. Should he then decide to qualify himself for useful work in the manufacture of iron and steel he is required to follow for three or four years a number of prescribed studies of mining methods, ore dressing, the metallurgy of the non-ferrous metals, while learning relatively very little of his chosen subject: iron and steel. His general scientific training is narrowed while the specialized knowledge acquired is not the kind he wanted.

He leaves college a less broad man than what he might have been with specific information in his chosen field too limited for immediate useful application. Nor can it be reasonably argued that six years is too long a period of time to devote to preparation for engineering work, for it would be an admission that professional work in applied science does not call for as broad and careful training as that now required by the best schools for the practice of law or of medicine.

Twenty years ago the science of metallography was practically unknown and it is only within the last fifteen years that it has been seriously considered by metal manufacturers and consumers as a valuable method of testing and investigation. That so much has been accomplished in so short a time is highly gratifying to the many workers, practical or scientific, who have contributed by their efforts to the progress of metallography.

To realize the practical importance of metallography it should be borne in mind that the physical properties of metals and alloys—that is, those properties to which these substances owe their exceptional industrial importance—are much more closely related to their proximate composition than to their ultimate composition, and that microscopical examination reveals, in part at least, the proximate composition of metals and alloys, whereas chemical analysis seldom does more than reveal their ultimate composition.

It will bear repeating that from the knowledge of the proximate composition of a certain industrial metal or alloy we are able to infer its properties and, therefore, predict its adaptability with a much greater degree of accuracy than if we knew only its ultimate composition.

The analytical chemist may tell us, for instance, that a steel which he has analyzed contains 0.50 per cent of carbon, without our being able to form any idea as to its properties, for such steel may have a tenacity of some 75,000 lb. per square inch or of some 200,000 lb., a ductility represented by an elongation of some 25 per cent, or practically no ductility at all; it may be so hard that it can not be filed or so soft as to be easily machined, etc.

The metal microscopist, on the contrary, on examining the same steel will report its structural, i.e., its proximate, composition, informing us that it contains approximately 50 per cent of ferrite and 50 per cent of pearlite, and we know at once that the steel is fairly soft, ductile and tenacious, or he may report the presence of 100 per cent of martensite and we know that the steel is extremely hard, very tenacious, and deprived of ductility.

Which of the two reports is of more immediate practical value, the chemist's or the metallographist's? Surely, that of the metallographist.

Nor is it only in the domain of metals that we find such close relationship between properties and proximate composition, for, on the contrary, it is quite true of all substances. How many organic bodies, for instance, have practically the same ultimate composition and still are totally unlike in properties because of their different proximate composition, i.e., different grouping

*A paper presented at the Congress of Technology at the 50th anniversary of the granting of the charter of the Massachusetts Institute of Technology.

and association of the ultimate constituents. If we were better acquainted with the proximate composition of substances many unexplained facts would become clear to us.

Unfortunately the chemist too often is able to give us positive information in regard to the proportion of the ultimate constituents only, his reference to proximate analysis being of the nature of speculation. Ultimate analysis has reached a high degree of perfection in regard to accuracy as well as to speed of methods and analytical chemists have built up a marvelous structure calling for the greatest admiration. Their searching methods never fail to lay bare the ultimate composition of substances. But how much darkness still surrounds the proximate composition of bodies and how great the reward awaiting the lifting of the veil!

The forceful and prophetic writing in 1890 of Prof. Henry M. Howe, M. I. T., '71, naturally comes to mind. Speaking of the properties and constitution of steel, Professor Howe wrote:

"If these views be correct, then, no matter how accurate and extended our knowledge of ultimate composition, and how vast the statistics on which our inferences are based, if we attempt to predict mechanical properties from them accurately we become metallurgical Wigginses. * * *

"Ultimate analysis never will, proximate analysis may, but by methods which are not yet even guessed at, and in the face of fearful obstacles.

"How often do we look for the coming of the master mind which can decipher our undecipherable results and solve our insoluble equations, while if we will but rub our own dull eyes and glance from the petty details of our phenomena to their great outlines their meaning stands forth unmistakably; they tell us that we have followed false clues and paths which lead but to terminal morasses. In vain we flounder in the sloughs and quagmires at the foot of the rugged mountain of knowledge seeking a royal road to its summit. If we are to climb, it must be by the precipitous paths of proximate analysis, and the sooner we are armed and shod for the ascent, the sooner we devise weapons for this arduous task, the better.

"By what methods ultimate composition is to be determined is for the chemist rather than the metallurgist to discover. But, if we may take a leaf from lithology, if we can sufficiently comminute our metal (ay, there's the rub!) by observing differences in specific gravity (as in ore dressing) in rate of solubility under rigidly fixed conditions, in degree of attraction by the magnet, in cleavage, luster, and crystalline form under the microscope, in readiness of oxidation by mixtures of gases in rigidly fixed proportions, we may learn much.

"Will the game be worth the candle? Given the proximate composition, will not the mechanical properties of the metal be so greatly influenced by slight and undeterminable changes in the crystalline form, size and arrangement of the component minerals, so dependent on trifling variations in manufacture as to be still only roughly deducible?"

The above was written before the days of metallography, or at least when metallography had barely appeared in the metallurgical sky and when no one yet had fancied what would be the brilliant career of the newcomer. Metallography has done much to supply the need so vividly and timely depicted by Professor Howe, precisely because by lifting a corner of the veil hiding from our view the proximate composition of metals and alloys it has thrown a flood of light upon the real constitution of these important products. Has the game been worth the candle? Will any one hesitate to answer in the affirmative Professor Howe's question?

Professor Howe with his usual acumen was conscious of the fact that proximate analysis, while likely to reveal a great deal more of the constitution of metals than ultimate analysis ever could, might still leave us in such ignorance of their physical structure as to throw but little additional light upon the subject. His fear was certainly well founded and surely if the proximate composition had been obtained by chemical analysis it would indeed have told us little of the structure or anatomy of the metals. In the domain of proximate composition chemistry can not do more for the metallurgist than it does for the physician.

Invaluable information chemistry does give without which both the physician and the metallurgist would be in utter darkness, but it throws little or no light upon the anatomy of living or inanimate matter. Its very methods which call for the destruction of the physical structure of matter show how incapable it is to render assistance in this, our great need.

The parallel drawn here between metals and living matter is not fantastic. It has been aptly made by Osmond, who said rightly that modern science was treating the industrial metal like a living organism and that we were led to study its anatomy, i.e., its physical and chemical constitution; its biology, i.e., the influence exerted upon its constitution by the various treatments, thermal and mechanical, to which the metal is lawfully subjected; and its pathology, i.e., the action of impurities and defective treatments upon its normal constitution.

Fortunately metallography does more than reveal the proximate composition of metals. It is a true dissecting method which lays bare their anatomy—that is, the physical grouping of the proximate constituents, their distribution, relative dimensions, etc., all of which necessarily affect the properties. For two pieces of steel, for instance, might have exactly the same proximate composition—that is, might contain, let us say, the same proportion of pearlite and ferrite and still differ quite a little as to strength, ductility, etc., and that because of a different structural arrangement of the two proximate constituents; in other words, because of unlike anatomy.

It is not to be supposed that the path trodden during the last score of years was at all time smooth and free from obstacles. Indeed, the truth of the proverb that there is no royal road to knowledge was constantly and forcibly impressed on the mind of those engaged in the arduous task of lifting metallography to a higher level.

Its short history resembles the history of the development of all sciences. At the outset a mist so thick surrounds the goal that only the most courageous and better equipped attempt to pierce it and per chance they may be rewarded by a gleam of light. This gives courage to others and the new recruits add strength to the besieging party. Then follows the well-known attacking methods of scientific tactics and strategy, and after many defeats and now and then a victorious battle the goal is in sight, but only in sight and never to be actually reached, for in our way stands the great universal mystery of nature: what is matter? What is life?

Nevertheless there is reward enough for the scientist in the feeling that he has approached the goal, that he has secured a better point of vantage from which to contemplate it. The game was worth the candle. And if scientific workers must necessarily fail in their efforts to arrive at the true definition of matter, whatever be the field of their labor, they at least learn a great deal concerning the *ways of matter,* and it is with the ways of matter that the material world is chiefly concerned. Hence the usefulness of scientific investigation, hence the usefulness of metallography.

Like any other science with any claim to commercial recognition, metallography has had first to withstand the attack and later to overcome the ill-will and reluctance of the so-called "practical man" with a decided contempt for anything scientific. He represents the industrial philistine clumsily standing in the way of scientific application to industrial operations. Fortunately, while his interference may retard progress, it can not prevent it. Had he had his own way neither the testing machine, nor the chemical laboratory, nor the metallographical laboratory, nor the pyrometer would ever have been introduced in iron and steel works.

In metallography, as in other fields of research, American workers, with very few exceptions, have been quite willing to let Europeans perform the arduous and generally unrewarded task of the pioneer, being content to wait before entering the

field until practical results were fairly in sight. Such course, which is never to be commended, becomes intolerable when accompanied, as it so frequently is, by the boasting attitude of the man believing himself smarter than his neighbor, whom he regards in the light of the cat drawing the chestnuts from the fire.

America, barring brilliant exceptions like Richards at Harvard and Noyes at Tech, does not as yet do her share of the pioneer's work in investigations which do not give evident indications of quick commercial returns. The unselfish, nay, self-sacrificing, spirit of the true scientist is of far rarer occurrence in the United States than it is in Europe, and especially in France. America has not yet produced a Pasteur nor a Berthelot, intellectual giants, profound scientific thinkers, whose conception of the duty of the scientist as a man is so lofty that they have despised the wealth within their easy reach to devote themselves unreservedly to the betterment of their country, or rather of the world, for they are morally so great that the entire world becomes their fatherland. Humanity claims them.

Speaking in 1904 of the practical value of metallography in iron and steel making, I wrote the following which it may not be out of place to reproduce here: "History, however, must repeat itself, and the evolution of the metallographist bids fair to be an exact duplicate of the evolution of the iron chemist; the same landmarks indicate his course; distrust, reluctant acceptance, unreasonable and foolish expectation from his work, disappointment because these expectations were not fulfilled and finally the finding of his proper sphere and recognition of his worth. The metallographist has passed through the first three stages of this evolution, is emerging from the fourth and entering into the last. For so young a candidate to recognition in iron and steel making this record is on the whole very creditable."

We may say to-day that he has definitely entered the last stage and that the adverse criticisms still heard from time to time, generally from the pen or mouth of ignorant persons, are like the desultory firing of a defeated and retreating enemy.

In the United States alone the microscope is in daily use for the examination of metals and alloys in more than 200 laboratories of large industrial firms, while metallography is taught in practically every scientific or technical school.

Harvard University.

The Florence-Goldfield mill was operated 365 days during 1910 and treated an average of 143.3 tons of ore per day. The total recovery of gold was 92.11 per cent; 58 per cent of this was shipped to the United States mint as bullion. The average cost of milling for the year was $2.085 per ton. The distribution of the total cost of milling for the year follows:

Amalgamating	$6,140.39
Assaying	1,740.60
Concentrating	12,490.45
Concentrating repairs	2,734.79
Crushing	16,704.57
Crushing repairs	9,716.57
Cyaniding	44,067.83
Cyaniding repairs	8,013.01
General superintendence and office	2,922.61
Mill superintendence	3,669.66
Power and lighting	37,038.38
Tailings	1,390.19
Watching	1,387.21
Water	6,934.24
Water repairs	377.02
Total	$155,327.52

In percentages of the total cost, the different items of cost are as follows: Cyaniding and cyaniding repairs 33.5 per cent, power and lighting 23.8 per cent, crushing and crushing repairs, 17 per cent, concentrating and concentrating repairs, 9.8 per cent, etc.

Modern Ore Dressing Practice in Gilpin County, Colorado.

By H. C. Parmelee.

A new standard has been set for concentrating mills in Gilpin County, Colorado, which is noteworthy because styles have not changed much there in the past forty years. The old milling methods, which were the result of varying conditions as to quantity and quality of ore, were just as simple and efficient as could be devised by the pioneers. Hence the development of the venerable slow-drop, high-discharge stamp mill, with inside

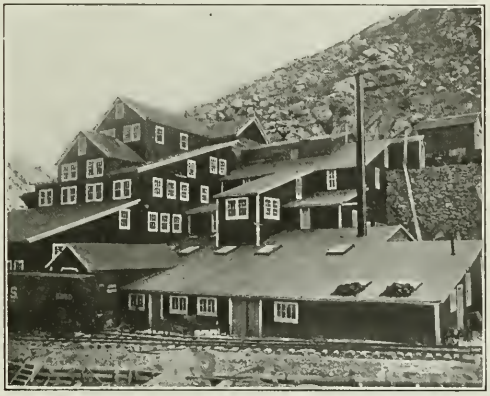

FIG. 1.—NEW 250-TON CONCENTRATING MILL OF THE FRONTENAC CONS. MINES, LTD., BLACK HAWK, COLO. OLD IRON CITY MILL IN RIGHT FOREGROUND.

amalgamation, for the treatment of surface quartz-gold ores and the Gilpin County bumper for the concentration of sulphides.

These devices probably were efficient in their day and for the class of ore they were designed to treat, but they do not adequately meet the demands of present practice. The inevitable change in other conditions has not been accompanied by a general disposition to abandon old styles of treatment and adopt new, even though the latter are of proved advantage. The tendency has been to hold to old methods, without always using the discrimination that marked their early use; the frank expression of some of the millmen being that "they are good enough." Under such conditions those who are progressive enough to depart from the old lines, even in the face of sceptical criticism, are entitled to credit and it is to be hoped that their example will be more widely followed.

The Frontenac Mill.

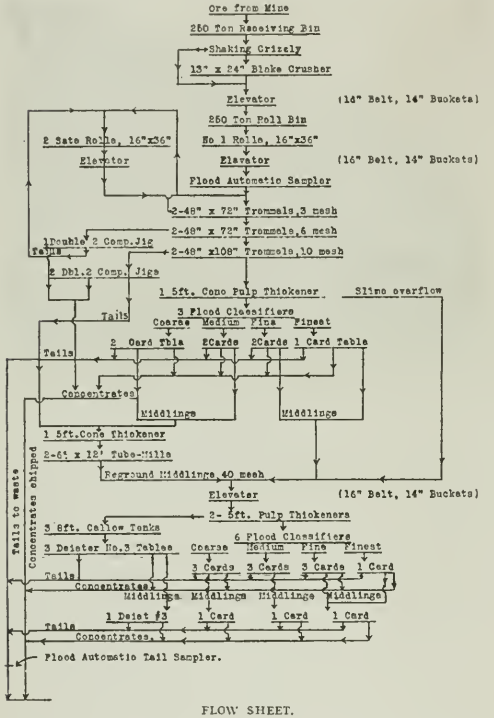
The Frontenac Consolidated Mines, Limited, an English corporation operating in Gilpin County, is represented locally by Mr. Henry P. Lowe, managing director. At his instigation the present Frontenac mill was built after two years' experimenting on methods of ore dressing to determine the best procedure and the most efficient machines. The mill, which is shown in Fig. 1, was designed by Mr. S. B. Tyler, general superintendent of the Frontenac company, and built by Peter McFarlane & Sons Iron Works Company, Denver. The view of the Frontenac mill also shows the adjoining Iron City mill in the right foreground. It was in the Iron City that Mr. Tyler conducted the preliminary experiments on Frontenac ore, testing several types of the various machines for long periods of time. The result is believed to be a rational system of treatment showing a marked advance in efficiency over former methods.

Frontenac ore is a mixed sulphide of iron, lead and copper, carrying gold and silver and occurring in a quartz and granite gangue. The minerals are mainly pyrite, with some galena and

tetrahedrite. The gold occurs mainly in the pyrite and the silver in the tetrahedrite. The pyrite and galena occur massive and are liberated from the gangue in condition for coarse concentration, but the tetrahedrite exists in thin seams and is not released save by fine grinding. This condition makes the recovery of the copper a difficult matter, as it is not until the ore is slimed that the highest saving can be made. The total value of the ore ranges from $8 to $10 per ton. The gold assays from 0.30 oz. to 0.35 oz. per ton; silver from 4 oz. to 6 oz.

Crushing, Screening and Jigging.

In general the system of treatment consists of crushing in stages, with intermediate concentration, beginning with the coarsest size at which mineral is liberated from the gangue, and ending with slime. Specifically concentration begins in coarse jigs on —3+6-mesh material and is continued in fine jigs, —6+10-mesh, and from there on three sets of tables with one intermediate regrinding.



FLOW SHEET.

The accompanying diagrammatic flow sheet shows the steps in the treatment. Ore is delivered at the head of the mill by the district tramway and dumped into a 250-ton receiving bin, from which it flows through ordinary rack-and-pinion gates to the coarse crusher. This machine is of the Blake type, and the largest in the district, having a jaw opening 13 in. x 24 in., and a capacity of 750 tons in 24 hours. All coarse crushing, therefore, is done on one eight-hour shift, which is ample to provide the tonnage for 24 hours.

The crushed ore, reduced to a maximum size of 2 in., is elevated to a bin of like capacity to the crude-ore bin. From here it flows to a hopper fitted with a plunger feeder which discharges to the roughing rolls. These are 16 in. x 36 in. in size, making 60 r.p.m., and set ¼ in. apart. Their product passes to an elevator which feeds the trommel screen line.

The trommel line is in duplicate, three trommels in each train; the first two are 4 ft. x 6 ft., and the third 4 ft. x 9 ft. Diagonal slotted punched screens are used, the first having 9 mm opening, the second 3 mm and the third 1½ mm, corresponding to 3, 6 and 10-mesh respectively. The oversize from the first trommel is returned to the regrinding rolls, of which there are two sets, 16 in. x 36 in., making 80 r.p.m., and set close together. The reground pulp is returned to the screen line.

The undersize of the first trommel passes to the second, and that of the second to the third. The oversize of the second and third trommels comprises the feed for the coarse and fine jigs respectively. The final undersize of the trommel line is classified for table treatment.

Three double two-compartment Traylor jigs receive the screen products as stated above. All jigs make hutch concentrates—a pyrite-galena mixture. The coarse jigs treat —3+6-mesh material. They are run at 220 r.p.m. with a ¾-in. stroke. They are fitted with 4-mesh screen of No. 15 wire. The fine jigs treat the —6+10-mesh pulp, have a speed of 280 r.p.m. and a stroke of 5/8 in. Their screens are 6-mesh of No. 13 wire. Coarse jig tailings are reground in rolls with the first trommel oversize and returned to the screen line, while fine jig tailings are reground in tube mills and treated in the slime department.

The jig concentrates are dewatered and delivered to a bin by means of a shaking launder having a perforated screen bottom for a portion of its length. The launder is suspended from above by 1-in. boards, and has a fall of about 1 in. to the foot. A knocker movement at the upper end throws the concentrates toward the discharge, dewatering them as they pass over the screen bottom. This is a device of Mr. J. J. Fitzgerald, mill foreman, who first installed it some years ago at the Humphreys mill, Creede, Col.

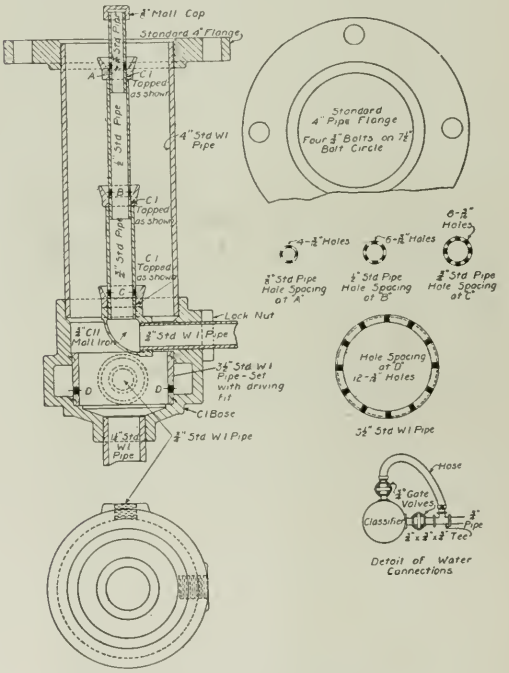


FIG. 2.—DIAGRAM OF FLOOD CLASSIFIER.

Classification and Table Treatment.

The undersize of the 10-mesh trommel is classified for table treatment by Flood classifiers. This device, which is illus-

trated in Fig. 2, is a hydraulic tubular classifier, several of which may be arranged in a launder to receive successively that part of the pulp not taken out by the one immediately preceding. It consists of a vertical tubular sorting column, with a centrally located water pipe entering from below, capped at the top and perforated with three annular series of holes for the escape of the hydraulic water.

As the pulp flows into the sorting column it encounters the upward current of water from the annular jets, and each particle of pulp sinking to the bottom of the tube must pass each series of jets before it can escape through the discharge spigot. That portion of the pulp which is too light to sink passes on to the next classifier, where the water pressure and discharge spigot are regulated to permit a further classification. Additional water is added through a circular chamber surrounding the bottom of the sorting column. This equalizes the pressure due to the height of the column and enables the classifying water to work without interference from counter currents.

These classifiers require only a small quantity of water, which is a consideration at the Frontenac mill. Further, they are not easily choked with foreign matter, nor do they permit the accumulation of a bank of solids at the top which, by becoming suddenly dislodged, may fall into the sorting column in a mass and escape classification.

Taking up the flow of ore from the last trommel, it passes to a thickening box, the overflow of which goes to the slime department and joins the tube mill discharge. The thickened underflow passes to three Flood classifiers, which give three classes of sand pulp and a fine overflow. These four products are treated on seven Card tables, each classifier discharge on two tables and the fine overflow on one.

Fig. 3 shows this section of the mill. This set of tables makes

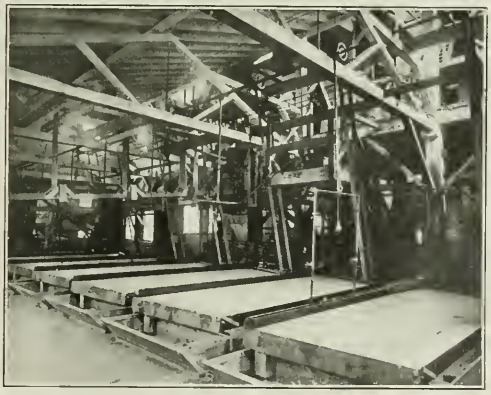

FIG. 3.—VIEW OF CONCENTRATING FLOOR FRONTENAC MILL, BLACK HAWK, COLO.

two concentrates, lead and iron. The former is rich in gold which has been liberated from the pyrite, while the latter carries some of the copper mineral, the specific gravity of which approaches that of pyrite. The slimes and middlings from these tables are retreated as shown in the flow sheet, the coarsest being first reground in tube mills with the fine jig tailings.

The use of the tube mill as a regrinder of middlings is still new in practice, although the idea seems to have been accepted as sound. By regulating the various elements which contribute to the net result it seems possible to get a wide range of products from the tube mill. Consistency of pulp, quantity of pebbles, size and speed of the tube can be so regulated as to make the mill adaptable to comparatively coarse grinding for concentration or to fine grinding for agitation in cyanide solution.

The tubes at the Frontenac mill, shown in Fig. 4, are 6 ft. x 12 ft. in size and are run at a speed of 21 r.p.m. They have silex lining and carry a load of about 7000 lb. of Norway pebbles. Only one tube is now in operation, and it is grinding about 60 tons of solids in 24 hours. The tube feed, as already stated, is the tailings from the jigs treating $-6+10$-mesh pulp and coarse middlings from the Card tables. The tube product is about 40-mesh material, with only a small percentage of -100-mesh. The machines have not been in regular operation long enough to give average screen analyses of the product.

The combined slimes and reground middlings are elevated, as shown in the flow sheet, to pulp thickening boxes, the underflow of which is classified in six Flood classifiers for

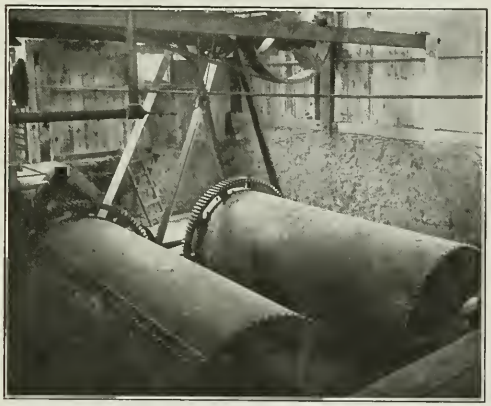

FIG. 4.—TUBE MILLS USED FOR REFINING TABLE MIDDLINGS AND JIG TAILINGS, FRONTENAC MILL, BLACK HAWK, COLO.

treatment on 10 Card tables. The overflow of the thickeners is further thickened in three 8-ft. Callow tanks for treatment on three Deister No. 3 slime tables.

Fig. 5 gives a view of the Callow tanks, with tube mills in the pit in the background, Card tables on the right and Deisters on the left. Owing to temporary water shortage the overflow of the Callow tanks is further clarified in thickening boxes and used for table wash water. The tables in this section make but one class of concentrates, practically all the galena having been removed in the jigs and coarse tables. Fig. 6 gives a view of part of the first division of the slime department.

Retreatment of the middlings from the Card and Deister slime tables is accomplished on additional tables of the same kind on a lower floor. These also make but one concentrate, which is richer in copper than the others owing to the naturally fine state of the copper mineral and its tendency to form slime.

Assays.

The following table gives average assays of the five classes of concentrate. It will be observed that the silver is nearly uniform throughout. Practically all the lead is removed in the jigs and first set of Cards, while the copper is recovered principally in the slimes. Each class is shipped separately on account of the varying percentage of silica which, according to smelter contracts on concentrates, is subject to a penalty when it exists in quantities above, say, 15 per cent.

	Gold oz. per ton.	Silver oz. per ton.	Lead per cent.	Copper per cent.	Silica per cent.
Jig concentrate	0.70	12.00	10.00	1.20	10.00
Card iron concentrate	0.60	11.00	.....	2.00	9.00
Card lead concentrate	5.00	12.00	37.00	....	.....
First slime department	0.45	12.00	.....	3.00	20.00
Second slime department	0.40	12.00	.....	3 to 4	30.00

The ratio of concentration is 4:1, and the percentage recovery, figured on shipments, is 85 per cent on gold, 78 per

cent on silver, and 75 per cent on lead and copper. This compares very favorably with recoveries of 70 per cent on gold and 60 per cent on silver when the same ore was treated by stamp crushing to 20-mesh and simple concentration in the Iron City mill.

Power and Water.

The mill building is of frame construction, steam heated and electric lighted. Electric power is received from the lines of the United Hydro Electric Power Company, Georgetown, Col.

FIG. 5.—CALLOW THICKENING CONES SHOWN IN RELATION TO TUBE MILLS AND ELEVATOR, FRONTENAC MILL, BLACK HAWK, COLO.

Six General Electric 440-volt induction motors are distributed as follows:

50 hp for crusher and elevator.

100 hp for three sets of rolls and two elevators.

25 hp for three double jigs, six trommels and seven Card tables.

20 hp for 13 Card and 5 Deister tables.

75 hp for two tube mills and elevator.

15 hp for Deming three-plunger pump, size 9 in. x 10 in.

The total power requirement has been found to be 176 hp at peak load and 150 hp on running load.

Water is obtained from Clear Creek, but can be used only after passing several settlement basins for the removal of sand and slime. It is then pumped to storage reservoirs on the hillside. Good water supply is a problem in this district, but the Frontenac company is making arrangements for an independent supply, which will be available probably this year.

The mill has been in operation since the middle of February, and at the time these notes were obtained had been running only five or six weeks. Hence it has been impossible to present some data, such as screen analyses, etc., which will be available later when those in charge have time for such details. Enough has been presented, however, to show a marked departure from former milling methods in this district, and acknowledgment is due to Mr. Lowe, Mr. Tyler and Mr. Fitzgerald for courtesies extended and information given for publication.

The Determination of Manganese in the Presence of Chromium and Tungsten.

By Thos. C. Watters.

The accurate determination of manganese in high-speed and air-hardening tool steel, or in any alloy steel containing chromium, has given the metallurgical chemist considerable trouble, both in the volumetric and color methods, owing to the fact that in oxidizing the manganese to permanganic acid part of the chromium present is oxidized to chromate and has an action similar to that of the permanganate upon reducing agents used in volumetric determinations and in the color method the yellow color of the chromate interferes with the pink produced by the manganese and destroys its accuracy. We are

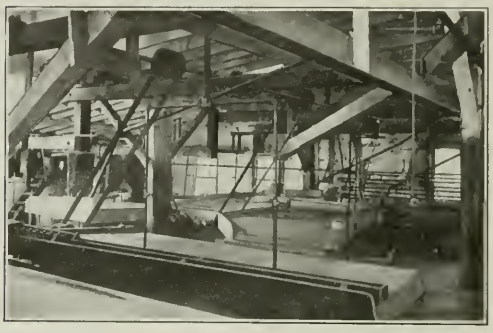

FIG. 6.—SLIME CONCENTRATING DEPARTMENT, SHOWING CARD AND DEISTER TABLES, FRONTENAC MILL, BLACK HAWK, COLO.

using a method in our laboratory which is a combination of the Volhard and bismuthate methods and are inclined to think the application original.

Two grams of drillings are dissolved in 20 c.c. of sulphuric acid (1.2 Sp. Gr.), enough water being added from time to time to keep the iron sulphate in solution. The solution when complete is oxidized by adding 5 c.c. of nitric acid (1.42 Sp. Gr.) and then evaporated until fumes of sulphuric acid are given off and the carbonaceous matter is destroyed; 100 c.c. of water are added and the solution of the ferric sulphate effected by boiling. The liquid and residue are washed into a graduated 500-c.c. flask and a solution of sodium carbonate added until the solution becomes dark in color and the precipitate formed by the addition of the carbonate dissolves with difficulty.

An emulsion of zinc oxide and water is then run into the flask a little at a time and the flask shaken after each addition until all the iron and chromium have been precipitated. The volume is then made up to 500 c.c. with water and the precipitate allowed to settle; 250 c.c., equivalent to 1 gram of sample, of the supernatant liquid is decanted, through dry filter and transferred to an Erlenmeyer flask. The solution is acidified with 25 c.c. of nitric acid (1.42 Sp. Gr.) and one gram of sodium bismuthate added.

It is well to shake the flask for several minutes after the addition of the bismuthate and then allow the residue to settle for a few minutes, after which it is filtered through asbestos, the filter pump being used. The flask and filter are washed with water containing a little nitric acid until free from the pink color of the permanganic acid. The filtrate is transferred to a beaker and a measured volume of ferrous sulphate solution, in excess of the permanganic acid, is dropped into the solution to reduce it. Its excess is titrated with a standard solution of potassium permanganate until a delicate pink color is obtained.

The ferrous sulphate solution should be made equivalent in strength to the permanganate. The difference between the num-

ber of c.c. of ferrous sulphate solution added and the number of c.c. of permanganate used to titrate the excess will give the number of cubic centimeters of permanganate which are equivalent to the manganese in the steel. By multiplying the number of c.c. of permanganate found by its manganese value the weight of manganese in the sample is found.

A solution of convenient strength for steel of low manganese content is made by dissolving one gram of potassium permanganate to a liter of water. It is standardized in the usual way, either with iron wire or ammonium ferrous sulphate, to find its exact value per c.c. in iron. Its iron value multiplied by the factor 0.1968 gives its value in manganese.

The ferrous sulphate solution may be made of such a strength as to exactly equal the permanganate solution, or, if not quite equal in value, a blank titrate is made and its value in c.c. of the permanganate solution found. Fifty c.c. of sulphuric acid to the liter will keep the ferrous sulphate from crystallizing out of solution.

I trust that this method of determining manganese in the presence of chromium may prove of value to others who desire to combine accuracy with reasonable speed, as it has to me.

Columbia Tool Steel Company,
Chicago Heights, Ill.

The Grinding and Screening of Clays.

The inherent difficulties in grinding and screening substances of a clayey nature have given rise to the development of machinery specially adapted to this purpose. The success of these machines in the various branches of the clay industry has led to their adoption also in some metallurgical plants where the conditions are exceptional and where the usual devices are not applicable. There has just been issued by the Geological Survey of Ohio *Bulletin* No. 11, entitled "The Manufacture of Roofing Tiles," by W. G. Worcester and Edward Orton, Jr., containing the latest data on actual practice in grinding and screening clays, from which we take the following excerpt:

The purpose in grinding clays preliminary to manufacture by the plastic process is twofold: First, to break up any obnoxious minerals which occur in coarse size and disseminate them through the mass; and, second, to create plasticity in clays in which that property lies dormant or undeveloped. While both purposes are probably accomplished in grinding any given clay, only one may be, and usually is, in view. Thus in soft, plastic clays there is need only of crushing and disseminating mineral impurities, while in homogeneous shales the principal requirement is the development of plasticity..

Grinding is practised both wet and dry. Wet grinding is used where defective plasticity is found, as it is the best known method for developing latent plasticity; but at the same time the method is inefficient in securing physical homogeneity. Hence this treatment is usually applied to hard shales and fire clays. In general, dry grinding is practised where the material is unhomogeneous naturally, and where its lack of homogeneity would cause trouble if not overcome. It is followed ordinarily by screening, which establishes the limit of size of the particles and insures uniformity. The dry screened clay is then converted to the plastic state by a subsequent process.

Thus it is seen that the wet and dry grinding processes are more than alternative routes to the same goal. The choice of treatment lies mainly in the judgment of the operator. The wet treatment is slower, more costly, and has less control of the homogeneity of the product, but produces far the best plasticity. In general any clay *can* be treated by this method, but it is uncommon to use save where necessary for the reasons given. The dry treatment is faster, cheaper, produces a more homogeneous paste, but of deficient plasticity. It can be used with clays of good or moderate plasticity, and wherever possible will be used for the reasons given.

The following observations on machines are from actual installations in roofing tile plants in the United States:

Rolls.—The roll is one of the simplest and oldest forms of grinding machines. Essentially it consists of two cylinders or cones whose surfaces are in close contact or held closely parallel to each other. Their axes must be in the same plane, and in the case of cylindrical rolls are parallel, but in the conical rolls the axes are inclined to each other by an amount proportional to the taper of the cones. Rolls are designed for two different ends: First, as a wet grinding machine for crushing stony, plastic clays, and for rejecting the rocks or hard portions which are too large to fall within the angle of nip; second, as a dry grinding tool for pulverizing large quantities of nearly uniform size of grains. The commonest use of rolls in this way is as a tailings grinder to finish the grinding of small particles which are partly reduced, but not enough so to pass the screens.

Wet Grinding Rolls.—At the plant of the Detroit Roofing Tile Company, Detroit, Mich., differential rolls are used for grinding a fine grained alluvial clay which is so plastic as to be difficult to grind in a strictly dry grinding machine like a dry pan. One roll is small and driven at a high speed, and the other is larger, driven at lower speed. They are set within a fraction of an inch of each other. The small roll, about 9 in. or 10 in. in diameter by 2 ft. long, runs at approximately 500 r.p.m., while the large roll, about 18 in. in diameter, makes but 150 r.p.m. The peripheral speed of these two rolls is quite different, so that when clay is fed into the machine it not only squeezes and crushes it, but also shreds and tears it apart as well. This machine is able to take clay either dry or wet and carry it through. As the clay falls from the rolls it is put through a pug mill and stored in aging bins. At another plant both rolls are of the same size, 2 ft. long and 30 in. in diameter, running at the same speed. These rolls also are followed by a pug mill, the combination being admirably suited to the needs, which are principally a thorough mixing of the different layers as they come from the pit and a thorough incorporation of an added ingredient which is foreign to the clay itself.

Dry Grinding Rolls.—The grinding of glacial clays presents a problem not found in alluvial clays and shales on account of the occurrence of boulders, gravel, sand, etc., which have been picked up by glacial action. Glacial clays are thus very heterogeneous in character, and their preparation offers a special problem. At one plant treating this kind of clay a pair of conical dry crushing rolls, smooth surface, set 1 in. apart, and running at 75 r.p.m., handles about nine tons per hour. In size they are 2 ft. long by 12 in. at the large end and 7 in. at the small. These rolls crush the lumps of clay and smaller pebbles; any stones that are too large for the angle of nip gradually work their way to the large end of the cones, where they fall out into a wheelbarrow and are removed. The use of these rolls is chiefly for their qualities as stone separators, but the next step in the process would hardly be successful if the clay had not first been crushed and shredded.

Dry Grinding Pans.—No other tool wholly takes the place of this as a rough-and-ready grinder, in which the material comes to it in widely varying sizes, degrees of hardness, degrees of plasticity and in rates of feeding. Irregularities in all these points may occur in any works and on every dry pan. No machine that cannot give a good account of itself under such conditions will ever displace the dry pan as a clay-grinder's main reliance. The step bearing which carries the weight of the vertical shaft is one of the most essential features about a dry pan. Usually a load of five to ten tons is carried on a bearing not as a rule exceeding 5 in. in diameter. This bearing tends to heat very easily and unless proper oiling facilities are provided it will be very short-lived. The principal thing is to secure positive and copious lubrication. Nearly

any step, if of adequate size, will stand well if kept thoroughly lubricated and clean. In selecting a pan one should try to secure one that is strongly and well built. By this is meant one that has every joint and bearing planed and fitted, every bolt hole drilled and machined bolts that properly fit the holes. There is not another machine about a clay plant that is expected to stand the rough usage that the dry pan is called upon to endure. It is entirely impossible to say that all the virtues are found in any one design, and there is no best pan in the sense of one filling all situations best.

Disintegrators.—A method of grinding not used in any other roofing tile plant in this country is found in the works of the National Roofing Tile Company, Lima, Ohio. Here a Williams pulverizer is used. The machine is not uncommon in other branches of industry, such as coal and cement. It consists of a horizontal shaft to which are keyed a series of disks, through the circumference of which bars are run, and on the latter are hung swinging hammers, which, by centrifugal force, fly straight outward on a line from the center of the shaft when the machine is rotated at high speed. The hammers strike a very powerful blow, but not being rigidly fixed are free to move backward when they encounter a body heavy enough to overcome the centrifugal force. Clay being subjected to such severe treatment as this is completely broken up before leaving the machine. It is found advisable to bring the clay to the disintegrator as dry as possible, and even then provision is made to steam-heat the jacket of the mill in order to prevent the clay from packing in it. For clays of a hard, compact nature, this machine will unquestionably break up massive lumps and reduce the whole to a powder, but if the clay be fat and sticky it would be impossible to work it in such a machine.

Screening.—After a clay has been through a pan or equivalent, and is in the form of a coarsely granulated powder, the screening still remains difficult if the moisture exceeds 5 per cent or 6 per cent. Caking on the screen, covering the holes, agglomerating and rolling on the surface without passing through, sticking in elevator cups, choking spouts and runways are troubles incident to dry clay screening.

The purpose of screening is to set a limit on the maximum size of particles. As the coarsest particles in a ground mixture also are likely to be the hardest, and also of different chemical composition from the matrix of fine aluminous material, it follows that these coarse particles are both difficult to grind finer and are the most injurious to the clay if not reground and made to blend well into the matrix. Screening is therefore necessary to establish a limit beyond which particles cannot enter the clay body except by accident. It is a very necessary part of the process of homogenization, of which grinding and tempering are the two principal steps.

On account of the troublesome nature of clays in the screening process, the actual size limit in clay plants is often much greater than is desired by the manufacturer, because without predrying he cannot either grind or screen effectively. Roofing tile clays in general are passed through from 12-mesh to 20-mesh screens or equivalent. Some form of the inclined screen, either stationary or movable, is most generally used.

Stationary Inclined Screens.—These consist of an inclined chute, the bottom of which is covered with punched plate, over which the pulverized clay passes. The size of the perforations and the angle at which the screen is hung govern the size of grain that will pass through it. Should the screen be horizontal particles the same size as the openings would pass, but upon elevating one end the particles attain a momentum and those passing through will be smaller and smaller as the angle of elevation increases. Hence, inclined screens are made adjustable as regards angle of elevation.

The fixed inclined screen gives considerable trouble through its tendency to blind, especially when the clay is damp. This means constant attention to secure effectiveness. Only one roofing tile plant in the country is using the fixed screen, and the material is a mixed sandy clay, screened through a 16-mesh screen, which is a little coarser than the average mesh used in this work.

Piano Wire Screen.—A recent form of inclined screen is made of heavy steel piano wires, strung on a strong substantial iron frame about 30 in. wide by 6 ft. long. The wires are drawn to a high tension and provision is, or should be, made to prevent slipping. At each end of the frame the wires are drawn over a rod threaded to suit the space required between the wires. By varying the pitch of these threads the mesh can be changed. The constant rigidity of the wires is an important requirement in order to insure regularity of the product. When properly constructed and kept in condition this screen has large capacity, does not blind easily, requires no power and little head room. In the roofing tile industry it has been found that on soft, easily slaking shale good results are obtained, while on hard, sandy shales the results are not all that could be desired.

The principal trouble lies in keeping the wires rigid enough to give a uniform product.

Traveling Inclined Screens.—The main difference between this and the stationary type is that the screening surface is composed of punched metal plates, constantly in motion on an endless chain. The object of the device is to bring automatically every part of the screen surface over a rotary cleaning brush, instead of depending on its being done by hand, as is the case with stationary inclined screens. The moving screen is made up of sectional screen plates, attached to sprocket chains on each side. These chains travel upward on the frame, over sprocket wheels at the top and down on the under side. A spreading board at the top delivers the clay onto the screen, after which it slides down over the plates which are moving in the opposite direction. Particles of proper size drop through the screen and the larger tailings flow over the end to be reground.

The screen plates may be made of piano wire or screen cloth instead of punched plates, if desired. The entire screen is hung so that its inclination can be changed in a few minutes. The rate of travel is not over 3 ft. or 4 ft. per minute. There are a number of advantages in this type of screen over others; it requires almost no attention, has a large capacity and will screen finer clay because it is always clean.

It has been found quite successful in screening ore as well as clay.

Centrifugal Screens.—One of these devices is in use at a plant at Alfred, N. Y. It consists of a large funnel-shaped receptacle, 4 ft. high, with a diameter of 9 ft. at its upper or large end. The screen is supported on a central shaft with spiders and suitable bearings at top and bottom, and revolves with the shaft. Clay is fed into the center of the rapidly revolving cage, and upon striking the bottom of the cone begins to move up the sloping sides of the cone by centrifugal force. The fine clay passes through the perforations, while the coarse material is carried up and over the top, whence it is returned to the rolls for regrinding.

It is claimed that this screen is giving excellent satisfaction in practice.

Visit of Pittsburg Railway Club to Ellwood City Works National Tube Company.—On Friday evening, April 28th, at the monthly meeting of the Pittsburg Railway Club, Mr. F. N. Speller, metallurgical engineer of the National Tube Company, read a paper on locomotive boiler tubes. In the afternoon of the same day the National Tube Company had invited the Pittsburg Railway Club to visit the Ellwood City plant where the members of this club had an opportunity to observe the manufacture of Shelby cold drawn steel tubes and Shelby hot rolled seamless steel tubes. The party was taken to the works by special train and luncheon was served going, in two large baggage cars. All members of the Pittsburg Railway Club had been invited.

Improvements in Cotton Bleaching.*

BY WALTER S. WILLIAMS.
Textile Expert, Arthur D. Little, Inc.

Bleaching is the whitening or removing of color from a substance, but in the textile industry the term is broadened to include the removal of all foreign bodies and coloring matter adhering to or included in the original fiber. In the case of fabrics it also covers the elimination of all materials, such as starch, oil and the like, added either intentionally or accidentally in the process of manufacture.

Cotton was used for the production of cloth thousands of years before the Christian era, and bleaching of the fabrics so made must have been more or less crudely performed even at that early age. While interesting, the scope of this paper will not permit the tracing of the early history of the art. Ancient processes will therefore be cited only as they may have some bearing upon modern practice.

An efficient process of bleaching requires a thorough understanding of the nature and chemical composition of the fiber and of the substances to be removed, as well as a knowledge of the effect produced by the different agents to be employed. It is a remarkable fact that very few complete studies of the process as a whole exist, and that the few careful investigations of different steps in the procedure have not received the attention and consideration they deserve at the hands of the practical manufacturers. There is no doubt that great progress will be made in the improvement of both processes and results by careful and scientific research in this field.

At the very outset of our study we are met by the fact that the chemistry of cellulose, which composes 83 per cent to 90 per cent of the crude cotton fiber, is still, after many years of investigation, far from being clearly defined. Two series of analyses conducted by the Department of Agriculture gave average results as follows:

FERTILIZING CONSTITUENTS.

Water	6.07
Ash	1.37
Nitrogen	0.34
Phosphoric acid	0.10
Potash	0.46
Soda	0.09
Lime	0.19
Magnesium	0.08
Ferric oxide	0.02
Sulphuric acid	0.6
Chlorine	0.07
Insoluble matter	0.05

PROXIMATE CONSTITUENTS.

Water	6.74
Ash	1.65
Protein	1.50
Cellulose	83.71
Nitrogen-free extract	5.79
Fat	0.61

ASH FROM COTTON.

Potassium carbonate	44.8
Potassium chloride	9.9
Potassium sulphate	9.3
Calcium phosphate	9.0
Calcium carbonate	10.6
Magnesium phosphate	8.4
Ferric oxide	3.0
Alumina and loss	5.0

Similarly, the precise change produced by alkalies and acids has not been determined and the extent to which such treatment may be carried without injuring the strength and lasting properties of the fabric is now rather a matter of observation and practical experience than an actual science.

For a knowledge of the impurities present in crude cotton we are indebted to a study of these bodies by E. Schenck. About 5 per cent of the original fiber is removed by boiling in soda ash for eight hours and may be thrown down from the resulting dark-brown liquor as a copious, light-brown precipitate by adding an excess of dilute sulphuric acid. If dried, it produces a brittle, horn-like mass which leaves upon incineration an ash varying from 2.3 per cent to 6.9 per cent.

From this residue Schenck succeeded in isolating substances which he classifies as follows:

1. A wax-like body which he named *cotton wax*. It is lighter than water, is soluble in ether and alcohol, but insoluble in water and only slightly dissolved by boiling dilute caustic soda.

2. A *fatty acid* which melts at 55.5° C. and may be either margaric or a mixture of stearic and palmitic acids.

3. Two nitrogenous, amorphous, brown *coloring matters*, one of which is easily soluble and the other sparingly soluble in alcohol.

4. *Pectic acid*, obtained in the form of a light-yellow amorphous substance resembling gum or gelatine. This body forms much the larger part of the precipitate, the other constituents being present only in extremely minute quantities.

5. Albuminous matter.

Many others have studied more or less thoroughly the nature of the substances extracted by water, ether or other solvents, as well as the nature of the ash present in the raw cottons, but without more definite results.

In cotton bleaching we are confronted with the problem of the removal of these various impurities and of the decolorizing or whitening of any yellow of brown tint still remaining. Broadly speaking, the process consists of boiling with alkili liquors to remove all impurities made soluble by such treatment and a subsequent oxidation for the removal of residual tint.

Cotton may be bleached in almost any form from loose or raw cotton to cotton piece goods, the difference in treatment required in each case being purely mechanical. As the bleaching of cotton piece goods far exceeds the importance of the bleaching of any other form of cotton, we will confine our attention to that form. We will also assume in the succeeding remarks a knowledge on the part of the reader of the terms and processes of practical bleaching.

The complete process used with slight modifications for the past 50 years may be outlined as follows:

1. Singeing.

2. *Gray Wash.*—Wet out in washing machine, allow to lie for 24 hours and wash.

3. *Lime Boil.*—Pass through milk of lime and boil for 12 hours under pressure.

4. *Lime Sour.*—Wash and pass through hydrochloric acid at 3° Twaddle, squeeze and allow to lie in sours for six to eight hours. Wash thoroughly.

5. *First Lye Boil.*—Boil six to eight hours with soda ash and resin soap. Wash in kier and through washer.

6. *Second Lye Boil.*—Boil in kier as for first boil, using soda ash and a small amount of caustic. Wash in kier and through washer.

7. *Chemic.*—Pass through hypochlorite of lime solution at ½° to 1° Twaddle. Allow to lie in chemic from six to eight hours.

8. *Sour.*—Wash and pass through sulphuric acid at 1° to 2° Twaddle.

9. *White Wash.*—Wash until all traces of acid are removed, open and dry. This process in practice will occupy from five to ten days.

The first step in the process of bleaching cloth for printing or other purposes requiring a smooth face is the operation of singeing, which has for its object the removal of all loose

*Presented before the Congress of Technology at the Fiftieth Anniversary of the Granting of the Charter of the Massachusetts Institute of Technology.

hairs from the surface of the cloth. This step is largely mechanical, but requires close attention to produce satisfactory results without damage to fiber or undue cost for gas or fuel. The most approved method, known as gas singeing, passes the fabric at speed several times through the flame of Bunsen burners extending the width of the cloth. Improvements in this step must come from proper regulations of the gas mixture and mechanical arrangement of rollers and speed of travel to produce the most efficient results.

The next operation is known as steeping, or gray washing, and consists in passing the goods through a washer or otherwise saturating, preferably with warm water, and allowing it to remain piled in a warm room from 18 to 24 hours. This treatment removes any bodies soluble in water and, as a result of fermentation, the starchy matters added as sizing.

Modern practice has made the mistake of considering this operation unnecessary and omitting it entirely even when the caustic boil is used. Lime probably removes the starchy matters completely, but it is extremely doubtful if more than a relatively small portion is extracted in the caustic boil. Steeping may be replaced by a malt treatment, using by preference one of the diastase preparations now on the market. The solution is prepared by using 15 lb. to 20 lb. of diastace or similar product to 100 gal. of water and warming to 140° Fahr. to 150° Fahr. The goods are wet out in this solution and the action allowed to continue for 15 to 30 minutes, then washed and passed to the next step in the process. Solubility of the starch may also be produced by wetting out with very dilute hydrochloric or sulphuric acid and piling for a short time. This process must be carried out with extreme care, owing to danger of the acid injuring the fiber.

Lime Boil.—The cloth is saturated with milk of lime of such a strength that it takes up about 4 per cent of its weight of CaO, run into one of the standard kiers and boiled with constant circulation of the liquor through the goods. This operation decomposes the fats and similar matter contained in the cloths and forms as a result insoluble lime soaps. These latter are broken up by the scouring which follows and completely removed by the subsequent operations. In addition, the other natural impurities of the raw cotton, as well as starch, are so changed that they either become soluble or are more easily acted upon by the chemicals employed in the succeeding processes.

The gray sours remove the excess of lime and other metallic oxides, if present, besides breaking up the insoluble soaps formed on the fiber.

The *lye boils* continue the reactions already begun in the lime boil and further saponify and remove any fatty acids resulting from the decomposition of the lime soaps in the previous steps.

Resin soap is employed by some bleachers and is supposed to remove certain indefinite constituents of the fiber which are said to have a deleterious effect on the whites of prints and are not fully removed by the other agents employed.

Bleaching or Chemicing.—The destruction of the coloring matter now left in the fabric is the object of this final step. Previous to the nineteenth century this was always accomplished by the exposure of the moist cloth to the action of air and sunlight, and extensive bleaching greens formed an important part of every establishment. The use of chlorine for this purpose was first proposed by Berthollet, about 1785, but its use even after the introduction of the hypochlorite of lime was very slow in becoming general. To-day, chlorine, either as calcium or sodium hypo, far exceeds all other agents in importance and in amount used. With proper regulation of strength of solutions and duration of action this bleaching agent may produce the most satisfactory whites without appreciable injurious action on the strength or other desirable properties of the fiber.

Large quantities of chlorine are annually produced electrolytically either as a gas to be absorbed by lime to form ordinary bleach or as hypochlorite of soda solution to be used direct. On a large scale the latter form cannot compete successfully with the cheaper and more common product, but it finds extensive use in laundries and in small establishments.

The sodium hypochlorite solution as made in this form of apparatus contains an excess of sodium chloride which causes the chlorine to be given off freely either to the fabric or the atmosphere. The solutions are, therefore, unstable and cannot be made in advance. The cost of production is also higher except in the case of cheap electric power and low freight rates for salt.

The much-claimed superiority of electrolytic bleach seems to have been based on the increased rate at which the chlorine was given off in the presence of the chloride and may be produced, if desired, in bleach from other sources.

The use of hypochlorite of soda made from bleaching powder and soda ash is highly to be recommended and in many cases will more than repay the increased cost. The following receipt for its manufacture is given by Thies and Herzig:

Two hundred and ninety kilograms of bleaching powder of 33 per cent available chlorine are ground to a paste with 1100 liters of water, and to this are added 175 kg of soda ash dissolved in 500 liters of water, and the resulting solution is immediately made up in 2000 liters. After stirring for one-half hour the mixture is allowed to settle over night and the clear liquor is decanted. The sediment is mixed with clear water, the clear liquor being decanted and this process repeated until in all 5000 liters of liquor are obtained, which should stand at from 6° to 6½° Twaddle. This solution is alkaline and is said to keep well.

In order to neutralize the free alkali and start the liberation of the hypochlorous acid, sulphuric or hydrochloric acid is added to the liquor just before using. Thies and Herzig recommend 6 grams to 7 grams of sulphuric acid of 60° Beaume for every 10 liters of the above bleaching liquor.

The kiers used in bleaching have had much to do with the progress of the art. Starting from open kettles heated by direct fire the natural tendency led to a large open kier, but heated by steam. A great improvement in this kier was the introduction of a central vomit pipe taking the liquor from the bottom of the kier and throwing it by means of a steam ejector over the goods at the top, thus producing a circulation through the goods. The next improvement was the introduction of the closed kier, by means of which the pressure and consequent temperature of boiling was increased.

The first distinct system was that of Barlow, whose kier was introduced about 1870. This system employs two kiers working in pairs and may use steam up to 40 lb. pressure. The liquor circulates from the bottom of one kier to the top of the other. In working with the Barlow system both kiers are filled with cloth as usual, the requisite quantity of liquor admitted and steam blown through both to expel the air through vent pipes. The kier is then closed and steam let into one only, so that the pressure at the top forces the liquor through suitable connection to the top of the other, where it is sprayed over the cloth.

When most of the liquor has been forced into the second kier the valves are changed so that the pressure is led to that kier, changing the circulation to the top of the first kier. This reversing process is continued until the goods are sufficiently boiled, when the kiers are blown out, washed and the process continued as usual.

The next great step in advance was the advent of the Mather kier, which was especially constructed by Messrs. Mather & Platt to carry out the process devised by Horace Hoechlin. In this system the lime boil is entirely dispensed with and this, as well as the two lye boils of the old process, are replaced by a single boil in caustic soda and resin soap. The kier used for this boil is a large horizontal cylinder with convexed ends, one of which may be removed to allow the entrance of the goods. Suitable means are provided for raising the door and for making the same steam-tight when closed. The pieces to be bleached are piled on wagons made of sheet iron with perforated

bottoms and running on tracks leading inside the kiers. When ready the wagons are run into the kier, the door is closed, the air driven out by steam and circulation started. While the kier is boiling, other wagons may be loaded and those already boiled unloaded, thus increasing greatly the production of a single kier.

The process aims to subject the fabric to the action of caustic liquor and steam at the same time and for this purpose the amount of solution used is small compared with the size of the kier. The circulation is maintained by means of a centrifugal pump, which takes the liquor from the space under the wagon and showers it over the top of the goods. It then percolates through the pieces and collects in the bottom of the kier, where it is heated by closed steam pipes and is again taken up by the pump, which maintains a continuous circulation. The kier may also be heated by the introduction of live steam, but the resulting dilution of the liquor is more objectionable in this than in other kiers.

Several ingenious continuous processes have been proposed for boiling cotton piece goods, but as yet no system of this character has succeeded in prolonging the treatment long enough to produce results comparable with those obtained by the more usual method.

The Thies keir and the process of which it forms a part are the result of long, careful research by Thies and Herzig. By designing the kier in such a manner that no steam comes in direct contact with the liquor and thus avoiding the action due to the oxygen contained in the air always present in steam, it is impossible to use strong caustic at a high pressure without fear of tendering the fabric. The latest form of kier consists of three parts—the kier proper, the vacuum boiler and the superheater. The vacuum boiler consists of an upright cylindrical vessel similar in size and shape to an ordinary kier, while the superheater is of the same height as the kier, but much smaller in diameter. The latter is provided with closed coils for heating. For the circulation and transfer of liquors use is made of a Grindle pump. The boiling consists of two parts and the process is described by the authors as follows:

The goods saturated with alkali (liquor blown off from the previous bowking) are packed into the kier and then by means of the Grindle pump the old kier liquor is drawn from the vacuum boiler (which is quite full to start with, and closed at the top) and sent in at the bottom of the kier until the latter is quite full, the air escaping through a blow-off valve at the top. As soon as the kier is full the air valve is closed.

By pumping the liquor from the vacuum boiler into the kier a vacuum equal to about 10 lb. is produced in the former vessel. A pipe provided with a throttle valve connects the top of the kier with the top of the vacuum boiler. This valve is now slightly opened, so that a circulation of the liquor takes place, while any air contained in the kier rises with the liquor, passes through the throttle valve into the vacuum boiler, where the liquor falls to the bottom and expands into the vacuum.

The pressure in the kier is now gradually increased to three atmospheres by choking the valve, when any air remaining in the goods is mechanically dissolved out of the goods (air being more soluble in water under pressure) and transferred to the vacuum boiler. After the air in the vacuum boiler has been expelled, steam is turned on in the superheater and the bowking continued for two hours at 45 lb. pressure.

The pump is now stopped, the steam turned off and the liquor blown off under its own pressure. Fresh lye, consisting of caustic soda at 6° to 7½° Twaddle and the resin soap, is now run into the kier (which is free from air), the pump set in motion again, steam turned on in the superheater and the bowking proper continued for six hours at 45 lb. pressure.

As free hypochlorous acid is much more efficient as a bleaching agent than any of its salts we find many attempts to make use of this property.

Mather and Thompson pass the cloth continuously through closed chambers in which the pieces are run through an atmosphere of CO_2 after being saturated with the ordinary bleaching solution. Acetic acid vapors have also been used in the same manner. The addition of small amounts of sulphuric or hypochloric acid or of acetic or formic acid to the chemic solution will produce similar results, and the improved action of the liquors will be at once apparent.

Chlorine in cotton bleaching may be replaced by other oxidizing agents and will no doubt be superseded at some later date by some agent acting less injuriously on the fiber itself. Such a body is found in sodium or hydrogen peroxides and it is only the higher cost which prevents its more general use. For cotton and silk goods, laces and other special fabrics, it finds extensive application.

Drawing freely from all published information, especially the results of the researches of Koechlin, Thies and Scheurer, the following process has been evolved as a working compromise of the theoretical and practical:

The goods are marked and sewed as usual and piled on trucks. They are then run through the gas singer and directly through a lukewarm solution of diastafor or other diastase and into a continuous piling chute—a more or less complicated inclined trough so arranged that while cloth is entering at the upper end and leaving at the lower a large amount of slake cloth fills the length of the incline and allows time for the action to take place. To increase the time of action, several of the chutes may be arranged in series, the cloth passing over a reel between each.

From this step the goods pass directly to a small washer and are then squeezed and piled in a bin. As wanted they are drawn through a saturating machine, where they are impregnated with caustic soda at 3° Twaddle, containing 0.5 per cent sodium bisulphite solutions and packed directly in the boiling kier.

This kier should be of the vertical pressure type with outside vomit pipes and pump circulation. The perforated false bottom should be conical in shape and so arranged as to give a much larger space at the bottom than is usually allowed, and should be provided with both closed and open steam pipes. The closed coil should be sufficient to maintain the kier at boiling during circulation after that temperature has been reached, and must be provided with a suitable trap to remove the hot water and return it to the hot well or feed-water heater.

The goods are evenly plaited and tramped in the kiers by boys in the usual manner to within 2½ ft. or 3 ft. of the top and anchored with nets or chains.

The air is replaced by admitting steam and a charge composed of 3° Twaddle caustic containing 3 per cent of resin soap run in to cover the goods. The kier is brought to a boil with the open coil at a pressure of 15 lb., a small vent pipe being open to allow the escape of air.

When the goods are boiling the open pipe is nearly closed and the boiling is continued for six to eight hours with the use of the closed coil as far as possible.

The charge is washed in the kier, care being taken to prevent access of air to the hot fabric. The pieces are then run out of the kier through a washer, squeezed and returned to another kier, where the boil is repeated, but with the omission of the resin soap.

Experience seems to indicate that two boils are necessary to produce a thorough bleaching without over treatment in the subsequent steps.

The goods are next run through the chemic and piled in open bins for two to six hours. The best results are produced at the greatest economy by the use of hypochlorite of soda prepared as already described, but with experience and care very satisfactory results are obtained by the use of hypochlorite of lime solution at ½° to 3° Twaddle.

Continuous processes which subject the fabric for a short period to a very strong chlorine solution or which sour the cloth after chemicing without previous washing are necessarily injurious to the fiber and unsatisfactory in other respects.

The pieces after lying exposed to the air for a suitable length of time are washed, soured through sulphuric at 1° to 2° Twaddle, washed twice, and are then ready for opening, drying and finishing as desired.

Bleaching to-day is not an exact science and depends for success upon experience combined with close observation and understanding of the various processes. If the heads of the industry in this country could be brought together for an interchange of experience and frank discussion of the most promising lines of research, a great advance would be produced in the art, but in any case we may expect sooner or later more economical and efficient processes to replace many of those now in use.

Boston, Mass.

American Foundrymen's Convention at Pittsburgh.

The annual convention of the American Foundrymen's Association, the American Brass Founders' Association, and the Associated Foundry Foremen will be held in Pittsburgh from May 23 to 26. More than 3000 delegates are expected to attend the convention.

At the same time the great exposition of the Foundry & Machine Exhibition Company will be held. The exhibits will fill more than 40,000 square feet of area.

The Pittsburgh committee in charge of the preparation for the convention has been very active. It consists of Mr. Joseph T. Speer, chairman; Mr. F. W. Zimmers, secretary; Mr. J. S. Seaman, chairman of the Finance Committee; Mr. H. E. Field, chairman of the Convention Committee; Mr. W. A. Bole, chairman of the Excursion Committee; Mr. George P. Bassett, Jr., chairman of the Ladies' Entertainment Committee; Mr. E. D. Frohman, chairman of the Ball Game Committee; Mr. Eliot A. Kebler, chairman of the Reception Committee, and Mr. W. B. Robinson, chairman of the Press Committee.

On Monday, May 22, registration of delegates will be started at the exhibition buildings. The formal opening will be on Tuesday, May 23, and at the joint meeting papers on production cost, economic foundry insurance, and uniform contracts will be presented.

In the afternoon of the same day there will be sessions of the American Foundrymen's Association (papers on unloading methods, on the use of borings in the cupola, on the effect of alloys in cast iron, and on permanent molds) and the American Brass Founders' Association (papers on vanadium in non-ferrous metallurgy, on determinations of nickel in bronzes, on pouring high-grade bronzes, etc.

A joint meeting will be held on Wednesday morning, May 24, with papers on rotary blowers, on foundry construction, on heating and lighting systems, on pattern making, and on molding machines, while separate meetings will be held in the afternoon by the American Brass Founders' Association and the American Foundrymen's Association.

On Thursday morning, May 25, another joint session will be held with papers on molding sand, on the use of alloys, on shot in castings, etc., while for the afternoon a great excursion to foundries and steel works around Pittsburgh has been arranged.

On Friday morning, May 26, separate sessions will be held by the different associations, with election of officers. In the evening of Friday the large official subscription dinner will be held.

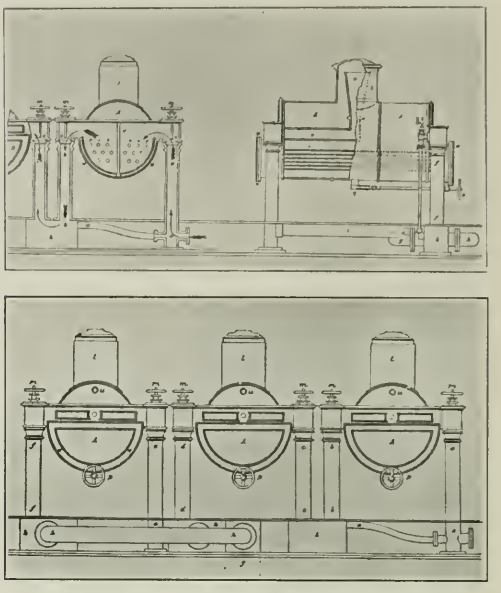
Evaporators and Vacuum Pans.

By B. Viola, M.E.,
Member American Society of Mechanical Engineers.

(*Continued from page 209.*)

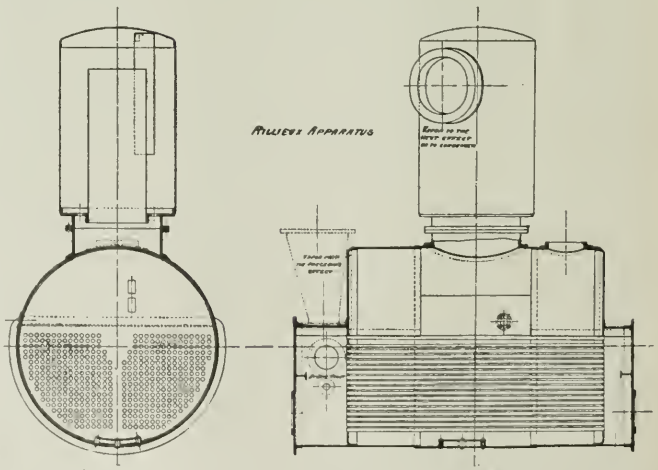
Evaporators with Horizontal Heating Pipes.

The originator of the present system of evaporation was Norbert Rillieux, who in Paris in the year 1830 first proposed



FIGS. 11, 12 AND 13.—ORIGINAL CONSTRUCTION OF RILLIEUX EVAPORATOR.

the construction of the multiple effect evaporator. It took, however, many years before the first one could be built and used by Rillieux himself in Louisiana in the year 1843.



FIGS. 14 AND 15.—MODERN CONSTRUCTION OF RILLIEUX EVAPORATOR.

According to the report to the Thirtieth Congress in 1848 this was a triple effect with wrought-iron heating tubes and

is shown in his original construction in Figs. 11, 12 and 13. It was composed of three cylindrical vessels made of sheet-iron plates 10 ft. long and 3 ft. 6 in. in diameter, made parallel and supported by cast-iron columns which are placed at each end.

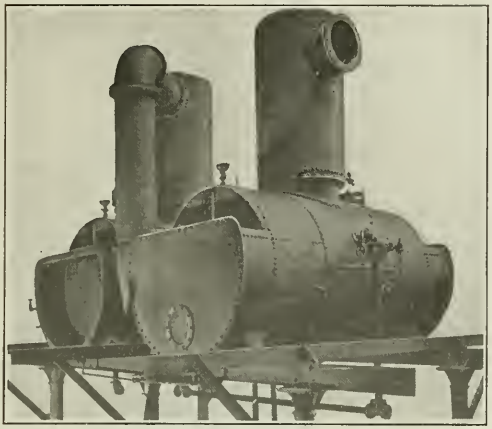


FIG. 16.—DOUBLE-EFFECT RILLIEUX EVAPORATOR.

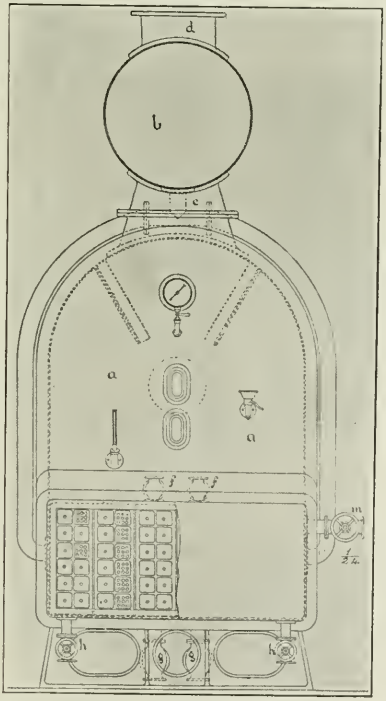

FIG. 17.—JELINEK EVAPORATOR—CROSS-SECTION.

The steam or vapor circulates in the interior and passes from one vessel to the other by means of a system of valves and pipes and each vessel is provided with a dome in which a cone-shaped connection is inserted for taking up the vapors of the juice and leading it to the next effect. The vapors from the last vessel pass to a condenser, where they are condensed by an injection of water. The vacuum is maintained by means of a large vacuum pump.

A modern construction of a Rillieux evaporator is shown in section in Figs. 14 and 15. Fig. 16 shows a complete double effect manufactured in this country. Rillieux's apparatus was introduced in Europe with the help of his foreman, Brami André, and in 1849 was constructed by Tischbein with horizontal, and later by Robert, in his sugar factory, with vertical heating tubes.

All the evaporators had disadvantages in that the steam chamber and the space for boiling were very small and naturally the surface of the liquid also, especially in the vertical constructions. Under these conditions, when the liquids were in the boiling state, the vapors carried away great quantities of small drops, thus causing immense loss.

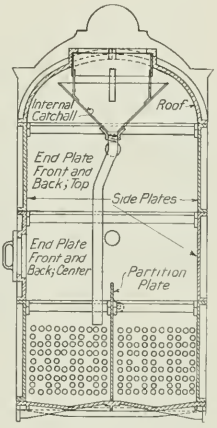

FIG. 19.—SWENSON EVAPORATOR.

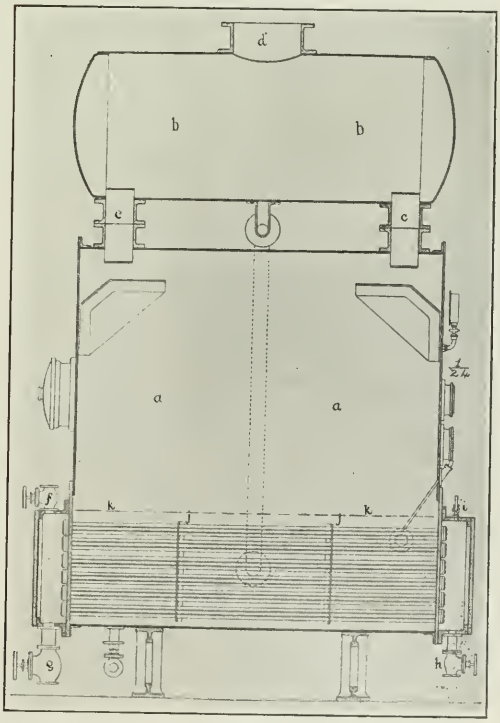

FIG. 18.—JELINEK EVAPORATOR—LONGITUDINAL SECTION.

The first improvement to avoid this loss was made by Hugo Jelinek. He constructed his evaporator with a rectangular

bottom and haf-cylindrical top, filling the lower part with a large quantity of heating tubes and making the apparatus very high on account of the large space above the boiling liquid. The liquid was always kept low, hardly covering the heating pipes, and in this way getting a high efficiency, Figs. 17 and 18.

We can see on both sides the so-called drop catchers which prevented the drops raised by the dome vapors to pass in the T on top of the apparatus. These catchers covered the vapor outlets and the drops raised by the vapors were knocked against them and fell back, the vapors passing out through the two outlets into the next effect or condenser.

A very efficient construction of the Rillieux type is the Swenson evaporator built in the United States and shown in section in Fig. 19. Fig. 20 shows how the heating tubes are made tight to the shells and Fig. 21 the disposition of a quadruple effect.

Film Evaporators.

As mentioned before steam bubbles in an evaporator rise to the surface with greater difficulty if a large body of liquor covers the heating pipes and naturally the boiling point is much higher in the bottom than at the top. To make the evaporation more efficient different evaporators were con-

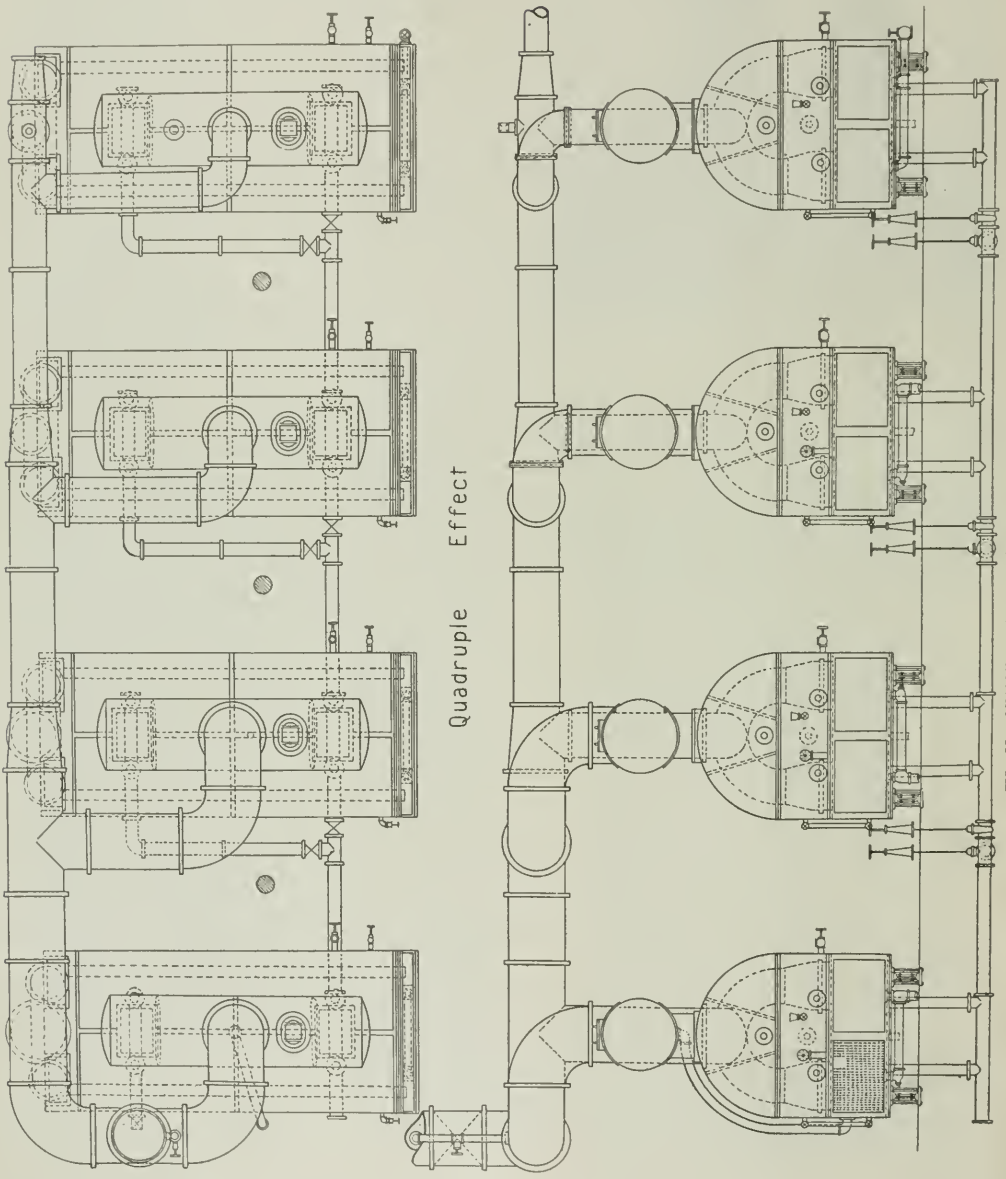

FIG. 21.—QUADRUPLE-EFFECT SWENSON EVAPORATOR.

structed to let the liquors run on the outer surface or the inner surface of the heating tubes in thin films or fine sprays.

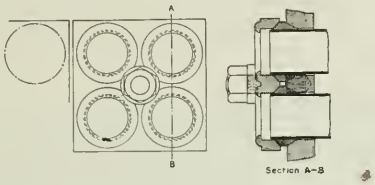

FIG. 20.—ARRANGEMENT OF HEATING TUBES.

We can classify them:

a. Film evaporators with horizontal heating tubes.

b. Film evaporators with vertical heating tubes.

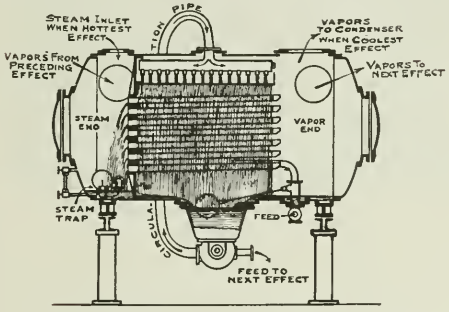

FIG. 22.—FILM EVAPORATOR WITH HORIZONTAL TUBES.

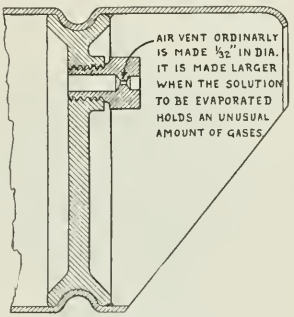
I will describe shortly those most in use at the present time having high efficiencies.

The Lillie Evaporator.

Fig. 22 shows an evaporator with horizontal tubes and mechanical circulation in longitudinal section. The evaporating tubes incline slightly downward toward the steam end and open through the heavy tube plate partition, in which they are firmly expanded (without annealing) and by which they are supported.

The other ends of the tubes are closed, save for a small air vent, Fig. 23, in each. They are not fastened or supported in any way, and the tubes are quite free to expand or contract independently of the shell of the effect.



AIR VENT ORDINARLY IS MADE 1/32" IN DIA. IT IS MADE LARGER WHEN THE SOLUTION TO BE EVAPORATED HOLDS AN UNUSUAL AMOUNT OF GASES.

FIG. 23.—AIR VENT OF A LILLIE EVAPORATING TUBE.

On the under side is a specially designed centrifugal circulating pump located midway between the ends of the evaporator and bolted to a well, which, however, is sometimes omitted, in which case the liquor rises sufficiently in the body to float the feed-valve ball float which regulates the feed into the body.

The condensation of the steam inside the tubes flows back into the steam end and thence through a steam trap into the steam end of the next cooler body and finally from the coolest body to the atmosphere, in the case of a multiple effect.

The circulation of the solution over the tubes is a deluging shower, maintained by the centrifugal pump. The circulation is independent of ebullition and there is no depth of solution on the tubes through which vapors must force their escape, as in all submerged-tube evaporators.

The small quantity of liquor in the body is indicated. It is comprised of that in the well beneath the effect plus the liquor flowing over the tubes.

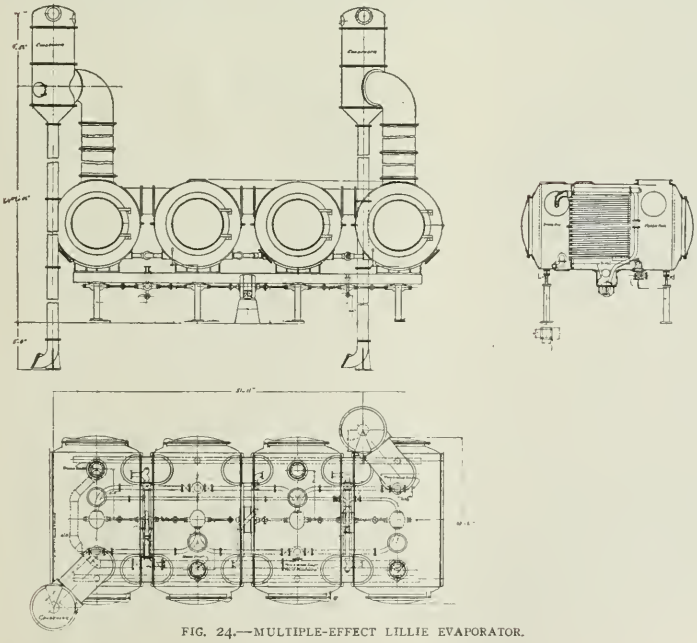


FIG. 24.—MULTIPLE-EFFECT LILLIE EVAPORATOR.

The perforated distributing plate above the tubes is formed in sections for convenience in handling. It has one row of holes 3/8 in. or more in diameter above each vertical row of tubes. There is a 1-in. space between the distributing plate and the tube plate, through which there is a heavy flow of solution upon the surface of the tube plate, which prevents matter caking on the tube plate.

There is also a 1-in. space on each side of the tube plate. The flow of the solution over the side edges of the plates carries with it the particles of scale that may come up with the liquor and prevents them from clogging the perforated plate. These matters pass away when the liquor is discharged from the body and in the case of a multiple effect, finally leaving the apparatus from the last effect.

The feed to the effect is automatically regulated by the feed-float valve to correspond with what passes away from the effect and consequently the liquor level is held practically constant. This is the usual method of arranging the vents for the escape of incondensable gases from the tubes. They are, however, differently arranged to meet different conditions.

These vents should occasionally be tried with a fine wire to see if they are open. A closed vent stops evaporation in its tube.

When combined to form multiple effects (Fig. 24) bodies are placed in line side by side and turned alternately end for end, so that the vapor end of a body is next to the steam end of each adjacent body; this permits short vapor connections between the bodies and the peculiar valve system employed for reversing vapors. The circulating pumps come in line and one shaft is employed common to all the pumps.

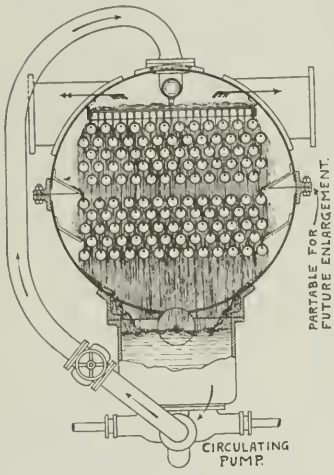

FIG. 25.—LILLIE EVAPORATOR BUILT FOR FUTURE ENLARGEMENT.

In addition to the circulating pumps the shaft usually carries a centrifugal pump for discharging the thick liquor and another for the condensation. All the latter comes away from the coolest body through this one pump. This shaft is driven by a motor or by a belt from an engine.

The multiple effects are arranged either for not reversing the direction of vapors through the system (the usual manner of working multiple effects) or to permit of reversing the direction of the vapors or heat through the system, which is strictly characteristic of the Lillie multiple effect.

Its operation is automatic. The feed of liquor into the first effect and from effect to effect and away from the last effect is automatically regulated by the feed-float valves, no matter what may be the number of effects, with the exception of the regulation of the density of the product by means of the valve in the discharge pipe for the latter. The water of condensation is automatically trapped from effect to effect and all passes away from the coolest effect through the centrifugal condensation pump.

A valuable feature of the Lillie evaporator is its capacity for enlargement, when bodies are constructed with that end in view. It is accomplished by parting the two semi-cylindrical halves of which an effect is composed when constructed for future enlargement and inserting between them a section of tubes carrying the tube surface which it is desired to add (Figs. 25 and 26).

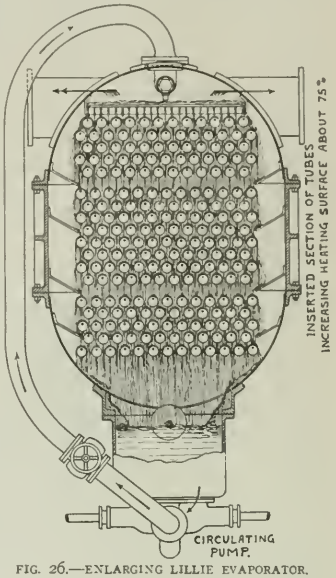

FIG. 26.—ENLARGING LILLIE EVAPORATOR.

The general arrangement for the reversal of vapors of the Lillie multiple effect or cutting out bodies in times of emergency are simple and almost automatically effected. By reversing the direction of the vapors scale does not form on the evaporating tubes, or if it does form it tends to crack and fall off from the tubes on account of the difference in expansion between the scale and the metal of the tubes under the changing temperatures. The time required for reversals is from 5 minutes to 15 minutes each.

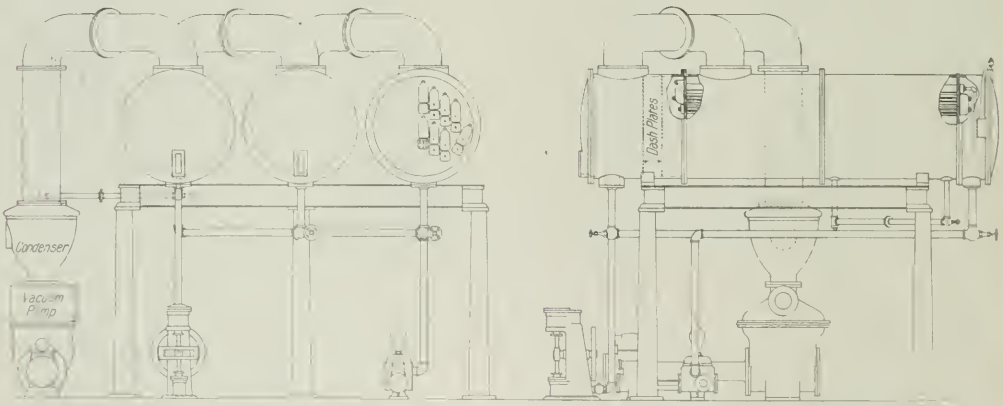

FIG. 27.—YARYAN EVAPORATOR.

The course of the liquor being concentrated is, as a rule, reversible. That is, it may be sent through the effects in succession in either direction, no matter what may be the direction of the vapors through the series. This permits taking the diluted solution into the coolest effect and delivering it concentrated from the hottest effect in cases when it is desirable to do so (when a liquid is to be brought to specially high densities).

Any effect can be cut out of the multiple effect and a quadruple effect can be arranged to run as two double effects.

The efficiency of the heating surface of the Lillie evaporator according to practical experience varies with conditions, but taking hot clarified cane juice and concentrating it to, say, 30 deg. Beaumé, it can be assumed that an evaporation of about 39 lb. per square foot in one body of a multiple effect, working with, say, 5-lb. pressure of steam to the first effect and an average vacuum in the coolest effect. This would be equivalent to about 10 lb. evaporation per square foot of total heating surface in the quadruple effect and about 13 lb. evaporation per square foot of total heating surface in a triple effect. The Lillie evaporator is used for water distilling and many plants are equipped with it.

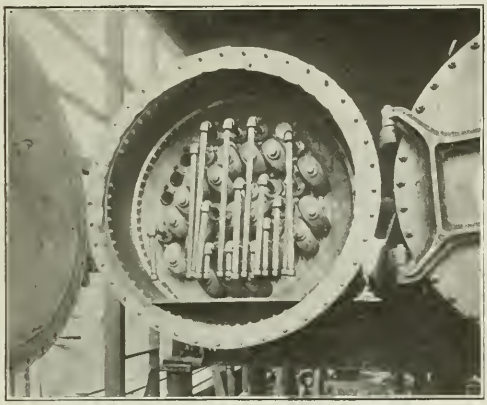

FIG. 28.—YARYAN EVAPORATOR. FEED CHAMBER.

The Yaryan Evaporator.

Under this name (Figs. 27 and 28) it is very well known and is now one of the oldest and very much improved evaporator systems with high efficiency. It consists of horizontal, cylindrical bodies with swinging doors at both ends and tubes packed into the tube sheets by return bends and packing glands, which makes it very easy to give the evaporating tubes a thorough cleaning, if necessary. Inside of these doors, as shown in Fig. 28, is a chamber in the front or liquor inlet side, and another chamber at the end or vapor side, where liquors and vapors leave the tubes.

The Yaryan evaporator is a combination of groups of evaporating tubes, each group working for itself. Between the two shells is the steam chamber and the evaporating tubes are there surrounded and heated by the steam.

Since the feed chamber (Fig. 28) for the vertical inlet pipes through which the liquor enters a pipe of larger diameter is surrounded by steam, the liquor begins to boil immediately and rushes with great velocity until it reaches the return bend (Fig. 27) and enters the pipe group with small diameters. By the rapid evaporation in the tubes great quantities of steam are formed which by their expanding force rush the liquid in broken-up streams of films through the pipes.

After these films pass the second return bend in the front they empty their contents with great force against the baffle plates, where the liquid falls to the bottom and continues its way to the next effect or the receiving tank, while the vapors pass over into the steam chamber of the next effect or to the condenser.

The Yaryan evaporator can be used to great advantage for water-distilling purposes as it concentrates any liquid that has a tendency to foam and also, on account of the ease with which the tubes can be removed and cleaned, it can be advantageously used for any liquid that scales the heating surface.

(*To be continued.*)

New York Meeting of the American Electrochemical Society

The nineteenth general meeting of the American Electrochemical Society, held in New York City on April 6, 7 and 8, was as successful and enjoyable as any that preceded it. For the first time the splendid new Chemists' Building was the gracious host of a national chemical society convention.

The attendance was good, more than 350 members and guests having registered. All the professional sessions, which were held in the spacious Rumford Hall of the Chemists' Building, were well attended. The papers presented were followed with unflagging interest and the discussions were lively and to the point.

No less interest was shown in the excursions which had been arranged for the three afternoons, including two of the largest and best-equipped copper refineries. At the works of the Nichols Copper Company, on Long Island, on Thursday afternoon, the smelting of copper ores and the bessemerizing of copper matte were shown, this being now the largest copper refinery in the world. Of even greater interest was the extended excursion on Saturday afternoon to the Perth Amboy works of the American Smelting & Refining Company, where the processes of electrolytic copper refining and of electrolytic silver refining were also shown, while in the purely metallurgical plant the latest departure of metallurgical practice—the bessemerizing of leady copper mattes in basic-lined converters—attracted naturally the closest attention.

For Friday afternoon a number of optional visits had been arranged, including an excursion to the new works of the Hanson & VanWinkle Company, of Newark, N. J., where the visitors were very cordially received and entertained, and the thoroughly modern and up-to-date demonstrating electroplating plant was shown which is used chiefly for demonstrating the company's mechanical electroplating apparatus for plating large quantities of work in bulk.

Another party visited the new interesting electric-furnace laboratory of Dr. F. J. Maywald, where both direct current and alternating current is available for experimental work with various types of electric furnaces, and the exceedingly well-equipped plant of the Moss Photo-Engraving Company, where the latest methods of photo-engraving and electrotyping could be watched in commercial practice.

Other parties visited the New York Testing Laboratories, which have already been described in this journal, and the laboratories of Columbia University and of the College of the City of New York.

A subscription dinner "en famille" on Thursday night was very enjoyable. Mr. Maximilian Toch distinguished himself as a most resourceful and witty toastmaster. On this occasion the secretary of the New York Section of the society, Mr. H. B. Coho, presented on behalf of the section a watch fob to Mr. Alois von Isakovics in recognition of his seven years' service as secretary-treasurer of the section and as chairman of the membership committee of the society. The fob was a copy—the first one struck off—of the new enameled gold emblem of the society. Other after-dinner speakers were Professor Walker, Dr. Whitney, Professor Richards, Mr. Sperry, Dr. Baekeland and Professor Bancroft. The dinner, which was a very happy, harmonious and informal affair, was attended by a large number of ladies.

Not less enjoyable, though in a different way, was the smoker on Saturday night. Mr. H. B. Coho, as master of the revels, was simply grand. He was ably assisted by Mr. Frank A. Pattison, whose acting was clear-cut art, and by Mr. J. M. Muir,

who managed the affair with great success from the outside. There were songs, presents, speeches, a raid, a newspaper, a love story, and refreshments.

Business Meeting.

The annual business meeting of the society was held on Thursday morning, when the reports of the secretary and treasurer were presented.

In the report of the board of directors, presented by the secretary, Prof. J. W. Richards, it was stated that the increase of the number of members was quite satisfactory, being 145 net during the year. The number of members is now 1294. The financial status of the society during 1910 is also very satisfactory. The excess of receipts above expenditures for the year was $1,176.40, from which the permanent investment fund was increased by the purchase of another $1,000 bond.

The result of the annual election of officers was announced as follows: Dr. W. R. Whitney, chief of the research laboratory of the General Electric Company, is the new president of the society. Mr. F. A. J. FitzGerald, Dr. E. F. Smith, and Mr. A. von Isakovics were elected vice-presidents. Dr. E. G. Acheson, Dr. W. D. Bancroft, and Mr. Carl Hering were elected managers. Dr. Joseph W. Richards was re-elected secretary and Mr. Pedro G. Salom treasurer.

Dr. Willis Rodney Whitney, the new president, was born in Jamestown, N. Y., on Aug. 22, 1868. He graduated from the Massachusetts Institute of Technology with the degree of B.S. in 1890 and obtained the degree of Ph.D. at the University of Leipzig in 1896. He was for a time instructor and associate professor of chemistry at the Massachusetts Institute of Technology. In 1904 he accepted the directorship of the research laboratory of the General Electric Company. In this position he has been directing an enormous amount of research work, two brilliant results of which may only be mentioned—the graphitized-carbon filament and the ductile tungsten filament.

Dr. Whitney made a short address, starting with a poem by Browning and ending with a few impressive and characteristic words on universal optimism. Optimism is a wonderful tool in bringing about results. Optimism leads a man to try things. About the carbon ion, if we can get carbon to go as ion into solution, we can make a carbon cell which would revolutionize all methods of generating electrical energy. The ordinary man will say this would be such an enormous result, hence it will probably not work. The optimist goes ahead and tries it. He knows that he has an even chance all the time and he concludes that he had better take the chance.

In the following we give a concise report of all the papers presented at the meeting.

Dry Cell Testing.

Instead of the report of the committee on standard tests for dry cells, which was not yet ready, a paper was presented by Mr. W. B. Pritz, of the National Carbon Company, of Cleveland, Ohio, on dry-cell testing. The author pointed out the nonuniformity in the tests of dry cells now being employed and emphasized that there is in no sense a relationship between service and short-circuit current. It is true that the amperage reading of a cell, coupled with a familiarity with the particular brand, does serve as a good indication of the age of the cell or the presence of any serious defect; however, the customer who judges solely from the short-circuit current is very apt to obtain very inferior quality, and still dealers state that at least 90 per cent of the customers who buy cells off the shelves demand that they be so read and in most cases select that brand giving the higher current.

The author emphasized the need for informing the customer and for standardizing the methods of carrying on dry-cell tests. In general (other than for purposes of research) there are but two reasons for desiring a test upon dry cells: 1. To ascertain what life may be obtained from a brand of cells in a certain service. 2. To ascertain which one of several brands will give the longest life in that particular service.

With the former object in view the knowledge is best obtained by actual use of the cells in connection with the appliance. The great majority of tests are carried on, however, with the second object in view, viz., the comparison of two or more brands of cells for use in a particular service. Where the amount of testing is large it is impossible, even where it is expedient, to use the actual appliances for testing cells, and it becomes necessary to devise testing methods and appliances such that results obtained therefrom shall be comparable to the results obtained from the cells when placed in actual service.

It is even questionable whether it is wise to go further and make the operating conditions not only comparable, but as similar as may be to the operating conditions of the service for

W. R. WHITNEY,
PRESIDENT AMERICAN ELECTROCHEMICAL SOCIETY.

which the test is intended since it is not certain that results of greater meaning are obtained from such strict adherence to service conditions.

In general Mr. Pritz advises against test of various brands of cells by connecting them in series and discharging them simultaneously. There are occasions, however, when this is the only method to employ. Especially is this true when test conditions cannot be held constant for the separate testing of various brands. By test conditions are meant length of contact, strength of current and temperature of the battery. It is much preferable, for instance, to use the series method of test upon an automobile than to test the various brands upon different machines or upon the same machine at different times.

Mr. Pritz then discussed the effect of temperature upon dry-cell testing. This effect is three-fold. Firstly, temperature affects the initial current. When cells have been standing in a very cold place they may give such a low amperage as to be unsalable, but when brought to normal temperature the initial current is quite satisfactory.

Secondly, the influence of temperature upon service is greater than is generally supposed. Where comparable results are desired it is of extreme importance that the two batteries be kept at the same temperature. The effect of temperature also varies with the nature of the service, high temperature giving longer service where the drain is heavy, while low temperatures are favorable for light-drain tests lasting over a considerable period.

Thirdly, of prime importance in dry-cell testing is a knowledge of the effect of temperature upon the rate of deterioration of cells when left on open circuit. To determine just what this

effect might be, a number of cells were stored at seven different temperatures. The following table gives the initial currents and the drop in amperage after 10 weeks, expressed as a percentage of the initial values.

Temperature.	Initial Amperes.	Per Cent Drop in Amperes in 10 Weeks.
5 deg. C.	18.1	4.4
25 deg. C.	22.0	10.0
35 deg. C.	21.0	19.0
45 deg. C.	22.8	25.0
55 deg. C.	23.0	52.0
65 deg. C.	20.5	71.0
75 deg. C.	21.0	98.0

The greatly increased rate of deterioration on open circuit at high temperatures no doubt accounts for the poor service obtainable at such temperatures when long periods of time are necessary for its completion. The cells should be stored in a dry, cool place, and not in the corner behind the stove.

The rating of dry cells was next discussed by Mr. Pritz. In regard to the terms in which the results of dry-cell tests should be reported there is some difference of opinion, some authorities contending that the ratings should be expressed as the number of amp-hours given by a cell under specified conditions to a certain working voltage value. Others claim that more practical meaning is attached to a statement of the length of time during which the cell is able to maintain its working voltage above the specified limiting value.

It is the opinion of the author's company that that method of rating should be used which gives to the consumer the exact information which he desires, hence they favor the rating of cells by the length of service of a given kind which they are capable of giving.

The consumer is interested in the length of service which he is able to obtain from a battery and not in the amount of energy given. At first thought it might appear that the amp-hour capacity of a dry cell bears such a relation to length of service that either method of rating would give the same information. Such is not the case, however. Differences in discharge rate cause vast differences in the number of amp-hours obtainable from the cell. For research purposes the watt-hour or amp-hour output of a cell is very useful, but as a practical rating for dry cells it is not satisfactory, especially from the standpoint of the consumer.

Mr. Pritz finally urges the adoption of standard tests and recommends the following two tests for telephone service and gas-engine ignition service respectively:

For telephone service he subjects three cells in series to a discharge through 20 ohms resistance for a period of two minutes each hour, during 24 hours per day and seven days per week, until the working voltage reaches the limiting value of 2.8 volts, the results being reported as the number of hours' service to this cut-off point.

For gas-engine ignition service a battery of six cells is connected in series with a 16-ohm coil, which permits an average drain on the battery throughout its life of approximately 0.5 amp. Readings of the working voltage are taken at intervals throughout the test, the most important reading, however, being the impulse of current which the battery is able to force through a ½-ohm coil connected in series with the ammeter and in parallel with the 16-ohm resistance. When this value at the end of a period of contact falls below 4 amp the battery is considered unfit for service and discarded. The test batteries are discharged for two hours each day, one hour in the morning and one in the afternoon. As a test for lighter service the battery may be subjected to two drain periods of one-half hour each.

Since it is often the case that quite an interval of time may elapse between the manufacture and installation of a cell in service, a knowledge of what may be expected during this period becomes of no little importance, hence an open-circuit or "shelf-life" test is quite essential.

The method for determining shelf life generally consists of reading the initial voltage and short-circuit current of a representative sample of cells, followed by current readings at intervals of one or two months, depending upon the nature of the cell in question. The ammeter for reading short-circuit current should be dead-beat, and with its leads should have a resistance of 0.01 ohm. Two 30-in. lengths of No. 12 lamp cord make very convenient leads.

The results are merely indicative of internal resistance and bear no definite relation to the service which the cells may give. However, this information, coupled with familiarity with a brand of cells, becomes a very good indication of its quality. It also serves to indicate any serious defects of manufacture.

The cells are kept on the shelf until the short-circuit current has fallen below 10 amp. This point is arbitrarily chosen, as it represents a point below which it would be difficult to market the cell. For practical purposes the results are expressed as the number of months during which the short-circuit current remains above this cut-off point.

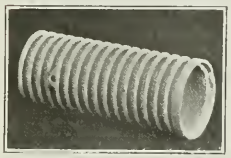

FIG. 1.—ELECTRIC FURNACE CORE OF ALUNDUM.

Much more meaning, however, is attached to the rate at which the current falls, generally reported as the drop in amperage expressed as a percentage of the initial amperage. This is especially true when investigation of the quality of cells is the object. For practical purposes, however, the first rating given, i.e., months to 10 amp, is perhaps preferable.

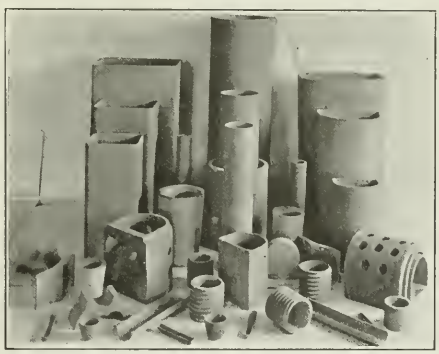

FIG. 2.—MUFFLES AND TUBES OF ALUNDUM.

The above paper having been printed in advance was read by title. There was no discussion.

Alundum Refractories.

Mr. L. E. SAUNDERS, of the Norton Company, of Niagara Falls, then presented a paper on electrically fused alumina (alundum) as a refractory. Alundum was primarily developed for abrasive purposes, but its heat-resisting properties were so often urged that it led to its introduction into this field.

There are two forms of alundum of interest in this respect: First, a white crystalline product, having less than 1 per cent of impurities, and, second, a reddish-brown vitreous material having from 6 per cent to 8 per cent of impurities, these consisting in both cases of oxides of iron, titanium and silicon. They are both electric furnace products from the mineral bauxite, having undergone different degrees of purification. The purer white product has a melting point between 2050° C. and 2100° C.; the brown product not more than 50° C. lower. The coefficient of expansion is linear and is, for the white product, 0.0000078 and for the brown material 0.0000085. The

thermal conductivity is about twice that of Marquart porcelain and three to four times that of most fireclay. The hardness in Mohr's scale is above nine, but lower than ten. The specific gravity in both products varies between 3.93 and 4.00. Both kinds of product are quite unattacked by aqueous acids and alkalies and very superficially by fused alkali carbonates. Basic or acid slags dissolve it with some difficulty, acid slags having a readier action.

Some attempts at molding it from liquid condition have met with partial success, although the difficulties involved are so great that only very simple and crude forms have been made.

FIG. 3.—ALUNDUM FILTER.

The method of application which has been found easiest consists in mingling the crushed grains (the purer form is mostly used) with a binding agent of a refractory and ceramic nature, molding the desired pieces after the manner of the potter and burning them in a ceramic kiln. The resulting articles are more refractory than the binding agents employed, and in nearly every case than amorphous alumina. This is also true of the unbonded product, even in fine powders, and it is a fact for physical chemists to explain. The amount of bond is varied in different forms, but in none of these articles does the melting point drop below 1950° C.

Other properties have changed but slightly. For instance, the temperature coefficient is in the more refractory bonded bodies 0.0000059. The thermal conductivity is still twice that of Marquart porcelain. The strength, both tensile and compressive, is very high even at high temperatures. The charge of electrical resistance with temperature as determined by Dr. M. deKay Thompson is as follows: at 535° C., 476×10^5 ohms; at 721° C., 49×10^5 ohms; at 908° C., 24×10^5 ohms; at 1040° C., 7.5×10^5 ohms.

Alundum muffles are distinguished by high thermal conductivity and high melting point. They have four to five times the life of the ordinary clay muffle in gas-furnace work. They are especially adapted to the electrically heated, wire-wound type of laboratory furnace. They have the advantage over quartz of being more refractory and of higher tensile strength. They are porous and cannot be used where entirely gas-tight furnaces are required.

Alundum tubes are similar to the muffles and have found chief use along the same lines. They are also porous and cannot be used for pyrometer protection tubes.

Alundum crucibles are made of varying density, but are still porous in all cases. This prevents their use in fusing slags or salts, but metals, even platinum, may be melted without injury to the crucible. This seeming disadvantage of excessive porosity has been turned to good account in the laboratory sizes. They answer all the purposes of a Gooch filtering crucible without the trouble of preparing the asbestos blanket, and the porosity can be so controlled that the most finely divided substances may be cleanly filtered. The usual analytical precipitates are quickly and surely separated and may be ignited quickly in the crucible on account of its high heat conductivity. Even deflocculated graphite may be separated from its suspending medium.

Large filtering dishes of alundum are also made and have been found useful in making organic preparations and in bacteriological work. An extraction thimble of alundum for the Soxhlet or similar apparatus is very useful as it may be cleaned simply by ignition over a burner and used repeatedly.

Alundum combustion boats of various sizes are valuable on account of good heat conductivity, mechanical strength and chemical inactivity. If it is desired to use a boat of some other material, some carefully prepared alundum grain free from carbon sprinkled over the bottom prevents the sample from sticking in an oxygen combustion.

A useful modification is alundum cement, which may be used to coat the inside of crucibles and furnaces for high-temperature work. It does not melt or combine with carbon below 1950° C. and may be used for lining larger sized crucibles than it has seemed practicable to make entirely of alundum.

There is a wide field of application, and it is possible to produce almost any shape that may be desired. Indeed the greatest difficulty so far encountered is that each user desires a different shape or size so that it has been impossible to prepare the usual stock.

Mr. Saunders had on exhibition a large collection of alundum articles. Mostly all of the forms shown were of laboratory or semi-commercial types. With respect to the larger commercial uses, Mr. Saunders said that by the very nature of the process of manufacture such a substance is costly and in excuse for the early development of the small articles, rather than more commercial forms, he stated that the cost of the material entering into their composition is relatively small, while in the case of bricks it is relatively great.

Some work has been done, however, on testing out alundum bricks. A Héroult furnace in the experimental department of one Niagara plant was equipped with a roof of these bricks in April last year. Since that time the furnace has been used at intervals totaling about three months' actual running time, with some forty or fifty shutdowns, and the roof is still in usable condition. The temperatures used are decidedly higher than in the steel furnaces, so high, in fact, that a regulation silica roof previously tried went down in five or six hours. A trial is now under way in the Héroult furnace of the Halcomb Steel Company, and so far the roof has been in use for twice the life of a silica brick one and is still in fine condition. Until this and other trials are complete no claims will be made for alundum brick. They cannot economically be used, however, in contact with slags, either acid or basic. Nor can they be usefully employed where the present refractory life is very long.

The paper of Mr. Saunders was discussed at some length by Messrs. Tucker, Lidbury, Hering, Hansen, Beckman, Amberg, Richards and Queneau. In reply to questions Mr. Saunders stated that he had determined the comparative melting points of seven commercial refractory bricks; they are in the order of their melting points from lower to higher temperatures as follows: silica brick, chrome brick, bauxite brick, brown magnesite A, brown magnesite B, Grecian magnesite, alundum.

As to the attack of alundum articles by ordinary laboratory reagents, Mr. Saunders stated that first treatment with H_2SO_4 and HCl takes off a little in weight from the alundum article, but never more than three hundredths of a per cent; later treatment takes away nothing. For this reason a preliminary wash of the alundum article is recommended.

As for certain purposes it is important to know the softening temperature rather than the melting point, Mr. Saunders stated that solid alundum does not soften within 100° of its melting point. Bonded articles hold together at 1950°, but would change their form under pressure at that temperature.

With respect to the use of alundum brick for roof construction of electric furnaces, Mr. Hansen pointed out the disadvantage of silica roofs in that they are liable to spoil the bath. The silica roof absorbs basic fumes which reduce the melting point Alundum is not thus affected, and alumina dripping into the furnace from the roof would not have the same disastrous effect as silica dripping into it.

Dr. Richards pointed out that the high thermal conductivity of alundum would make it an excellent material for zinc retorts. To prevent heat loss through the alundum roof of electric furnaces the roof would be jacketed.

New Resistance Furnace.

An account of a new resistance furnace, designed originally by Mr. John Thomson and Mr. Francis A. J. FitzGerald for carrying out the Imbert electric zinc smelting process, was the subject of a paper of Mr. F. A. J. FITZGERALD, of the Fitz-Gerald & Bennie Laboratories, Niagara Falls, N. Y. This furnace has already been noted in our Vol. VIII, pages 289 and 317 (1910).

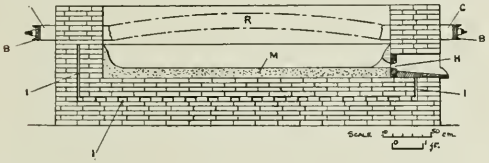

FIG. 1.—LONGITUDINAL SECTION OF RESISTOR RADIATION FURNACE.

If zinc sulphide and metallic iron are heated together to a sufficiently high temperature, the following reaction occurs:

$$ZnS + Fe = Zn + FeS$$

It appears, however, that this reaction is incomplete unless there is a large excess of iron present, or unless the temperature of the reaction is very high. Imbert discovered[1] that by using suitable "dissolvents" this objection to the process is overcome. For example, he found that ferric oxide and iron sulphide mixed together in the proportion of one part and three parts respectively formed a very fluid bath at a temperature between 1000° and 1100° C., and that this bath would "dissolve" six parts of blende. Now, when the zinc blende is "dissolved" in a bath in this way and treated with iron, the reaction given above is complete and works very easily, the zinc being given off as vapor and a residue obtained, which consists of two parts: a slag formed of the gangue of the ore and iron sulphide, which may be used for the regeneration of iron, etc.

The experiments made by Imbert were satisfactory, but the process is obviously not suitable for the ordinary zinc retort, and it was thought that an electric furnace might be used with economy. Experiments with various electric furnaces were tried, and finally the kind which forms the subject of this paper was devised.

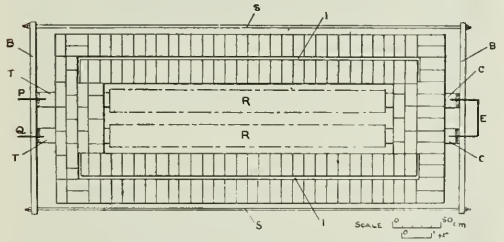

FIG. 3.—PLAN OF COVER OF FURNACE.

The conditions to be met by the furnace are as follows: It is desired to obtain a bath of molten iron, to which can be added a mixture of the zinc ore and the "dissolvent." The furnace must be gas-tight and must be constructed with sufficient ruggedness to withstand high temperatures and rough usage over prolonged periods. It must also be so designed that the temperature can be readily controlled, and finally the heat losses must be reduced to a minimum.

The first furnace constructed had an oblong reaction chamber, which was roofed over by the resistor. This was built of carbon rods laid transversely across the top of the reaction chamber, the ends of the bottom row of rods resting on ledges built of magnesite brick. The resistor was in contact with the furnace terminals, which were situated at either end. A charging door was provided under one terminal, while the tap-hole was under the other. The melting chamber of this furnace had a capacity of 250 kilograms (550 pounds) of iron.

Several experiments were made, but the most important was one lasting 3 days, 5 hours. During this experiment a quantity of pig iron was melted in the furnace, and it was found that with a temperature in the bath of 1300° C. the radiation loss was about 18 kilowatts. Since the full working capacity of the furnace was 40 kilowatts, the efficiency at 1300° C. was 55 per cent, which is not bad considering the small size of the furnace. This experiment was ended by keeping the current at 40 kilowatts without charging anything, the object being to find out how the furnace would finally fail under the increasing temperature. As was expected, failure occurred through the fusion of the magnesite bricks which supported the rods of the resistor.

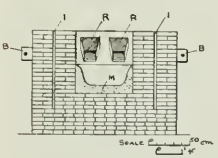

FIG. 2.—CROSS-SECTION OF FURNACE.

After the furnace had cooled it was taken down and examined, with the result that an interesting observation was made which gave a good notion of the temperature finally obtained in the bath. The reaction chamber was lined with Dixon's graphite-clay mixture, used in making crucibles, and it was found that this had been largely converted into amorphous silicon carbide.

Various critics of a furnace built according to this plan have pointed out that an unsatisfactory feature is the risk of fusing the cover. Presumably the heat radiated from the top of the resistor, which, of course, is just underneath the roof, would be so great as to be very severe on that part of the furnace. This objection, however, is not serious, for the current density at the lower part of the resistor is greater than at the top. The carbon rods forming the lower part of the resistor are in much closer contact than those in the upper part, on account of the weight of the upper carbon rods, consequently the resistance of the lower layers of carbon rods is less than that of the upper layers. The fact that the magnesite bricks below the resistor were fused at the end of the experiment, while the roof, which was built of a good grade of ordinary fire brick, was unharmed, shows clearly the difference in temperature between the upper and lower parts of the resistor. Moreover, by means of pyrometers actual determinations were made simultaneously of the temperatures in the bath and in the space between the top of the resistor and the roof. These showed that when the bath had a temperature of 1500° C. the temperature in the space above the resistor was only 1250° C.

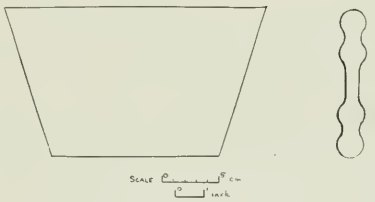

FIG. 4.—RESISTOR CONSTRUCTION.

In view of the fact that the final failure of the furnace was due to the excessively high temperature reached at the end of the experiment, it was concluded that for the lower temperatures required in working the zinc process, no difficulty of this kind would be encountered. Accordingly, a furnace having an estimated capacity of 150 kw was designed. In order to obtain a sufficiently high resistance in the resistor it would have been necessary to give this furnace a length considerably greater than its width, which would be objectionable on account of the relatively large radiating surface that would result.

[1] U. S. Patent, 875,579; Dec. 31, 1907.

Consequently, the furnace was constructed with both terminals at one end and the resistor in two sections connected with each other at the end of the furnace opposite the terminals by a graphite connector. One side of each section of the resistor was then supported on a ledge running along the side of the furnace, while the other sides were supported on a series of arches spanning the center of the reaction chamber in a longitudinal sense. By this arrangement a nearly cubical form was given to the furnace, and consequently the radiating surface reduced to a minimum. The inside dimensions of the reaction chamber were approximately 1400 mm (55 inches) square and 250 mm (10 inches) deep. The resistor was built of rods 19 mm (¾ inch) in diameter and 500 mm (20 inches) long. There were seven layers of these carbon rods in the resistor, each section of which was approximately 1140 mm (45 inches) long.

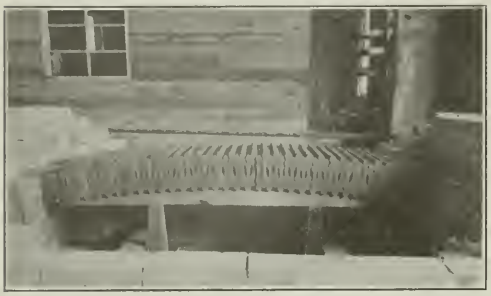

FIG. 5.—RESISTOR PLATES ASSEMBLED.

The experimental work on the zinc process was carried out at the plant of the Hohenlohe Works A. G., Hohenlohehütte, Upper Silesia, where the electrical apparatus was installed and the furnace constructed under Mr. FitzGerald's supervision The electric current was supplied to the plant at 6000 volts, and was transformed by a special transformer. The construction of the plant and the carrying out of a long series of experiments occupied over three months, and the results obtained with the furnace were satisfactory. The highest temperature actually measured in the furnace was 1460° C., but higher temperatures were certainly obtained.

Very interesting experiments were made on the heat losses of the furnace. During one part of the experiments the furnace was held at a constant temperature of 1250° C. to 1260° C. for over three days. During this time the furnace contained a bath of pig iron, and was absolutely idle, so that the energy generated was used simply for supplying the heat lost by conduction and radiation. The rate of generation of energy, when an absolutely constant temperature both in the bath and walls of the furnace was reached, was 33 kw. If, therefore, the furnace is working at 150 kw and a temperature of 1250°, the heat losses would be 22 per cent.

Another experiment was made which lasted 12 hours, and during this time the temperature of the bath was maintained at about 1450° C. Unfortunately, the temperature of the furnace as a whole was not constant at this time, for the temperature of the walls increased 100° during the experiment. The rate of generation of energy during this period was 42 kw, which, working at 150 kw, would give a loss of 28 per cent.

It must be noted that the heat insulation of this furnace was not by any means as perfect as it could be made. The thickness of the walls in the upper part of the reaction chamber was only 340 mm (13½ inches). That a much more efficient use of the heat generated could be made by more careful attention to heat insulation was demonstrated by later experiments.

The chief weakness shown by the furnace was in the magnesite bricks which formed the supports for the ends of the resistor carbons. The temperature of the resistor is very high, as was shown by making determinations of the density of the carbons forming the resistor after they had been in use. This shows that temperatures at least as high as 1900° C. were reached in the resistor itself.

In the experiments made with the Imbert process it was shown that the most satisfactory temperature for carrying on the reaction was between 1350° C. and 1400 C. in the bath, which would not require these excessive temperatures in the resistor. Neverthless, it was seen that the work had to be carried on too close to the limitations of the refractories, and this led to the development of a furnace of a different model.

In working the Imbert process the furnace is filled simply with vapor of metallic zinc, consequently there is no danger of burning the resistor carbons. The charging devices are so arranged that air is not introduced into the furnace, so that the zinc vapor does not burn to zinc oxide which would, of course, attack the carbon of the resistor. If, however, the furnace is used for other purposes it might be necessary to protect the resistor from combustion. For example, if a furnace is desired for copper melting it would be inconvenient and complicated to make arrangements absolutely to exclude air. It is better to enclose the resistor in a chamber, the bottom of which forms the roof of the melting chamber, and then make this resistor compartment air-tight.

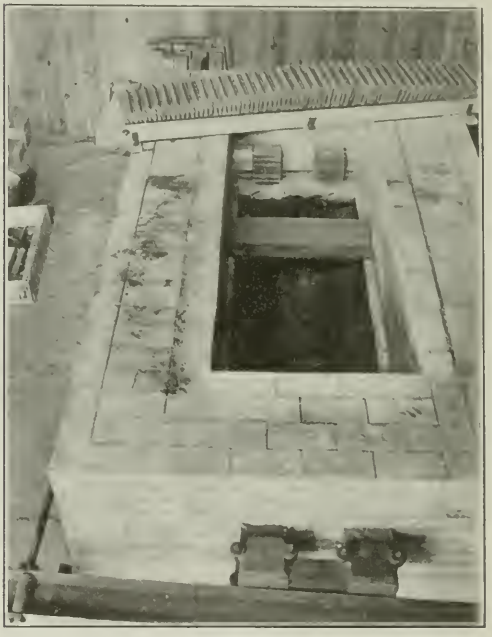

FIG. 6.—TOP OF FURNACE.

A great many experiments were made to determine the best material for forming this combined floor and roof, which requires above all two qualities: refractoriness and high heat conductivity. The result was the choice of recrystallized silicon carbide tiles. These are found to be satisfactory and to last well, even under severe usage. It would obviously be difficult to construct the resistor chamber so that it would be perfectly air-tight, so to prevent all possibility of oxidation it is desirable

to introduce an inert or reducing gas into the resistor chamber and to maintain this atmosphere slightly above external pressure.

A simple method, employed with success in experimental furnaces, is to put a long pipe in the cover of the furnace and mount on this a large oil cup with a sight feed. The oil cup is filled with kerosene, which is allowed to drop slowly into the resistor chamber so as to keep the latter continually full of oil gas. In one furnace constructed in this way after two months' continuous running the current was cut off, the furnace allowed to cool down and the resistor chamber opened. The resistor was found to be in excellent condition, though a few repairs to the terminals were necessary. The resistor chamber was then closed and the furnace is still running in a satisfactory manner, so that altogether the furnace has been working, with slight repairs, more than four months. This particular furnace had been used for a great number of experiments at temperatures varying from 1000° to 1500° C. (1830 to 2730° F.).

In a furnace constructed with the separate resistance chamber several experiments were made on melting aluminum, copper, monel metal, and iron, but the value of these was qualitative rather than quantitative. The furnace walls were only 230 mm (9 inches) thick, consequently the heat losses were so great that the furnace was not by any means efficient. The object of the experiments was to study the weak parts of the furnace. They confirmed what had been already observed, viz., the weakest part of the furnace was the support of the resistor.

The new model of the furnace is illustrated in Figs. 1 to 5. Fig. 1 is a longitudinal section of the furnace, the cover not being shown. Fig. 2 is a transverse section, and Fig. 3 a plan with the cover removed.

The walls and bottom of the furnace are cellular as well as the cover, so that it is almost completely surrounded with an air jacket as shown at I in the Figs. T,T, C,C, are carbon plugs which pass through stuffing boxes in the end walls of the furnace, T,T are the terminals of the furnace and are connected to the cables indicated by P and Q.

C,C are simply connected electrodes which form the other terminals of the sections of the resistor R,R and are connected by E. Bearing on the terminals T,T and the connector electrodes C,C are the channels B,B, which are connected to each other by the tension rods S,S and are insulated from the carbons. The lining of the furnace is shown at M and the taphole at H.

The resistor R,R is constructed of corrugated plates (Fig. 4), where the section is shown on the left and the form in which the plates are cut on the right. In Fig. 5 is a photograph of the plates set up to form the resistor. Referring to Fig. 4 it should be noted that the thickness of the corrugated plate is not the same at the top as at the bottom, but increases from the bottom up, so that when put in place they form an arch as shown in Fig. 5.

This arch form is not necessary, since the interlocking of the corrugated plates holds up the resistor perfectly well without any arch, but it seems to be desirable in the preliminary assemblage and also permits us to obtain a greater current density on the lower surface of the resistor.

By constructing the resistor in this manner all contact with refractories is avoided, the support being furnished by the carbon terminals. The form of the plates is not, however, solely designed to provide an interlocking device, but also to give a high contact resistance.

In one of these furnaces which was built for zinc smelting at Hohenlohehütte, O. S., there were 71 of these plates in each section of the resistor. The dimensions of the plates were as follows:

Length at top	405 mm	(16 inches)
Length at bottom	255 "	(10 ")
Width	165 "	(6.5 ")

When cold the resistor had a resistance of 0.200 ohm and when running at the full capacity of 150 kilowatts and with a temperature in the furnace of 1400° C. the resistance was 0.075 ohm. Now, if the resistance of the carbon itself is calculated it is found to be only 0.00064 ohm, consequently 98 per cent. of the total resistance is due to the contacts between plates.

In order to run a furnace of this kind it is necessary to have means by which a variable voltage can be applied to the terminals of the furnace. If the current is supplied at high voltage and has to be transformed there can be no doubt that the most satisfactory electrical apparatus is something in the nature of an induction regulator which permits of a continuous variation of voltage over a considerable range; but satisfactory results may also be obtained with a transformer from which several taps are brought out from the primary coil, so that the secondary voltage can be changed in a series of steps.

Both for the furnaces built at Hohenlohehütte and those in the FitzGerald and Bennie Laboratories transformers built by the Pittsburg Transformer Company are used with great success. These transformers have a capacity of 150 kilowatts and have 22 taps brought out from the primary coil. Leads are brought out from the two secondary coils and go to a switch so arranged that the coils may be connected either in series or parallel. When all the turns of the primary coils are in circuit the e.m.f. at the terminals of the secondary coils is 50 volts. Then as the turns are cut out of the primary coils the e.m.f. at the terminals of the secondaries is increased in steps of 2.5 volts until a maximum e.m.f. of 100 volts is obtained. By this arrangement there are obtained at the terminals of the furnace voltages of 50 to 100 in 2.5-volt steps and 100 to 200 in 5-volt steps.

When the furnace described above is to be used with an oxidizing atmosphere in the melting chamber the resistor is in a closed compartment, the floor of which is made of recrystallized carborundum plates or graphite plates coated with recrystallized carborundum to prevent them from burning. Fig. 6 is a photograph looking down into one of these furnaces and shows the two terminals and a few of the plates which form the bottom of the resistor chamber in place. The photograph also shows one section of the resistor mounted in clamps and ready to be put into the furnace.

Some anxiety was felt in regard to this design for a rather obvious criticism was that there would be a considerable loss of heat in passing from the resistor chamber to the melting chamber. In other words the thermal conductance of the side walls and top of the resistor chamber would approach that of the bottom of the resistor chamber in spite of the high conductivity of the latter.

Fortunately these fears proved to be groundless, for in the case of the furnace shown in Fig. 6 it was found that with a temperature of 1160° in the resistor chamber there was a temperature of 1090° in the melting chamber, and with a temperature of 1400° in the resistor chamber a temperature of 1290° in the melting chamber. In this particular furnace the heat insulation of the side walls and top of the furnace was not good, owing apparently to the high conductivity of the refractories employed, so the thermal conductance was higher than it should be.

Mr. FitzGerald believes that this furnace will find various useful applications. It apparently gives excellent results in the melting of copper, brass, aluminium, etc. It has not yet been tried for glass melting, but it is thought it will do this work well. Finally Mr. FitzGerald pointed out that the design of this furnace is such that it lends itself readily to the combination of fuel and electric heating. Preliminary experiments in this direction have been carried on and the results are highly satisfactory.

Mr. FitzGerald's paper was discussed by Dr. Whitney and Mr. Carrier. The latter asked as to the advantages of a resistor heater as a radiator over an arc. Mr. FitzGerald replied that with an arc the temperature is definitely fixed to a certain

extent and is higher than is necessary in many cases; further, there are electrode consumption and electrode troubles.

Replaceable Unit System of Electric Heating.

Mr. Milton M. Kohn, of the Multiple Unit Electric Company, of New York, presented a paper with demonstrations on a new replaceable unit system of electric heating. The essential features of this system have already been described on page 229 of our April issue. In this abstract, therefore, only such new points as were brought out in Mr. Kohn's paper are given.

Mr. Kohn pointed out that in comparison with the use of electricity for lighting and power purposes the amount of electric power employed for heating is practically negligible, although electric heating has the advantages of cleanliness, ease of handling, adjustability, and high efficiency. Mr. Kohn finds there are two reasons for this, first the comparatively high cost of electric current, and second the certainty of the electric heating device burning out sooner or later, no matter how carefully it may be used. This latter disadvantage is practically overcome in Mr. Kohn's replaceable unit system, as any heating unit which may burn out can be quickly replaced, as described in our April issue.

Some essential features of his system are summed up as follows: In the first place there is no special chamber used, nor is there one required, except for extremely fine and delicate work, the units themselves forming the chamber. In the second place the resistor is placed in units which have open slots towards the inside of the furnace, so that while the resistor is protected from mechanical and electrical injury which might result from the work which is placed in the furnace, it is still in such a position as to give off its maximum heat to the work, thereby giving greatly increased efficiency.

In certain industrial work, such as burning color on china, glass and similar material, there are pieces, such as very thin plates, plaques and other fragile shapes, where the heating should not be uniform because of differences in cross-section. In other words the same heat applied to the very thin almost knife edges of such work will almost certainly burn or melt the color off it, whereas that portion which is the thickest can safely stand a higher temperature. By the unit system of construction it is a very easy matter to so control the temperature on that portion of the furnace that the narrow or thin edges of the work can be heated very much slower or at a lower temperature, if desired, than the thick or body portion.

Again, in the laboratory work for the heating of various liquids, gases, etc., it is sometimes desirable to have the heating only on one side of the receptable, which may be a tube, flask or other differently shaped device, for the purpose of watching the work while it is being heated. To this end Mr. Kohn employs either a standard unit or a special one built for the particular work in question, which can furnish just the proper degree of heat and at the exact spot where it is wanted.

Another example is afforded by cases where it is desirable to have a "progressive heat." That is to say, that the heat should start very gradually at one end, and increase by successive stages up to the maximum. This can also very easily be done by using a unit of the required shape and length and so placing the convolutions of the heating medium that the heat will be progressive or gradual as required.

Again, by the unit system of construction the heat can be made absolutely uniform throughout the entire structure, or by various methods of connecting the units with and without resistance, which latter can be a part of the unit, a separate resistance in the furnace proper, or an external resistance, or a combination of all three of them together, the heat control can be made as gradual as may be required for the most delicate work.

As to the flexibility of construction, Mr. Kohn gave the instance of a muffle furnace in which the housing or body consists of a number of sections of refractory material; these are formed to make the desired shape, four of them generally being in a layer and possibly three layers being required to make a standard length of furnace. If it is desired to increase the length of the furnace all that is necessary is to increase the number of layers so that there is no limit to the length, except that caused by mechanical strength. The units which fit into this furnace are made in the same way; additional lengths can be added so as to make the required length.

In order to increase the cross-section of a furnace of this character all that is necessary is to insert between the corner pieces which make up the housing or support for the units a distance piece of the required dimensions by means of which the cross-section can be indefinitely increased, the limitation being mechanical. The units are increased in the same manner by inserting a special shaped distance piece, which has the same cross-section as the unit with which it is to be used.

The system is also well adapted to making special heating devices to conform to any specially shaped article that it is desired to heat. For laboratory work hot plates for sand baths, etc., can be made of any size or shape, and to give any desired temperature and any heat control by a simple combination of standard sizes of units and different combinations of circuits. For domestic use this type of construction has an unlimited field.

Another feature of value for domestic and laboratory use is that by means of units which are wound for the various standard voltages it is not necessary to have separate complete devices, but only an extra set of units, so that where a device has been purchased to operate on a 110-volt circuit the purchase of an extra set of units wound for a 220-volt circuit will enable the same device to be used on the higher voltage, everything else remaining the same as before.

Mr. Kohn exhibited some standard types of his furnace and purposely burnt out some units in one of the furnaces in operation in order to show how quickly the burnt-out heating units can be replaced and the furnace restarted.

In the discussion Dr. J. W. Richards criticised the black outside of the furnace and stated that if it was painted white with aluminium paint it would result in a saving of 10 per cent of the heat to keep up the same temperature. Dr. Patten described some experiments of his own with replaceable heating resistor units.

Electric Furnace for Heating Bars and Billets.

Mr. Thaddeus F. Bailey, of the Bailey Engineering Company, Alliance, Ohio, presented a paper on his new electric furnace for heating bars and billets. This method had suggested itself to him when noting the very wasteful and thermally inefficient oil-fired furnaces for heating forging stock used in a comparatively modern plant in northern Ohio.

A calculation of the thermal efficiency of the furnaces in question, which were said to be of the most modern construction, showed that less than 4 per cent of the heat value of the fuel was delivered into the steel.

Mr. Bailey's electric furnace, which is shown in Figs. 1, 2, 3, is of the resistance type, and consists essentially of two carbon electrodes, spaced from each other, and an intermediate resistance body of a carbonaceous composition in which the heat is generated. In the space directly above the resistance material and directly under the roof of the furnace is placed the metal to be heated, a ledge at the rear of the furnace and one at the opening supporting the bars or billets, as the case may be.

The electrodes enter the furnace through the rear wall, and are placed slightly convergent, so that the path of the electric current will be shorter from electrode to electrode at the front of the furnace than at the back. This arrangement compensates for the cooling effect, which is greater at the front of the furnace on account of the opening and the charging of the cold material.

The electrodes entering the furnace from the rear present

comparatively large contact surfaces to the resistance material, without the use of special electrode sections. The electrodes are also placed in a plane above the resistance material, which throws the shortest path for the electric current in the upper part of the resistance body and nearest the metal.

This is a feature that seems almost indispensable to the successful operation of a furnace of this character, since in the furnaces constructed without this feature the cooling of the upper

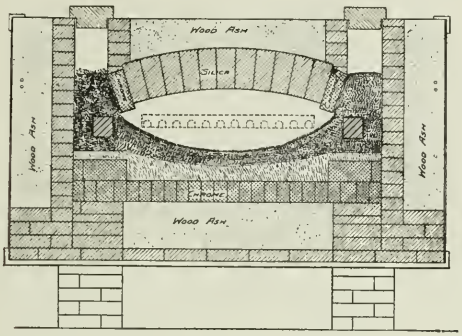

FIG. 1. VERTICAL, RIGHT-LEFT SECTION

part of the resistance body by the cold steel caused the electric current to take a lower path, in which portion of the body the temperature became very high and melted out the bottom linings and the bottom of the furnace itself, and at the same time did not maintain the heating chamber at a temperature high enough to heat the metal.

The resistance material is composed of coke or coal. Crushed foundry coke passing over a 0.25-in. (6-mm) ring and through a 0.37-in. (9-mm) ring giving the most satisfactory and uniform results. For a 40-kw furnace, heating 150 lb. (69 kg) of metal per hour, the distance between electrodes should be 36 in. (90 cm) and the cross-sectional area about 24 sq. in. (150 sq. cm). To maintain an electrical input of 40 kw a voltage of 200 would be required with a coke resistance body; if the body is composed of coal, the voltage should be about 150 volts.

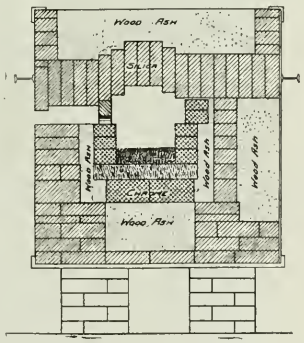

FIG. 2. VERTICAL FRONT-BACK; MIDDLE SECTION.

It is extremely difficult to determine the effective cross-sectional area of the material through which the electric current passes, as at working temperatures the lining materials become almost as good conductors of electricity as the resistance material itself.

The resistance body as it approaches the electrodes has a very greatly increased cross-section, so as to provide a better contact with the electrodes, prevent undue heating at the point of contact, and prevent, to as great an extent as possible, the dissipation of heat through resistance to the passage of the current except at that part of the resistance body directly under the metal.

The most serviceable lining material used by Mr. Bailey is made of chrome brick and chrome ore. The top of the furnace is composed of silica arch brick, and is 9 in. thick, and clamped from front to back. A row of chrome arch brick is placed at each side of the roof to prevent contact of the silica brick with the carbon in the hoppers above the electrodes.

The sides of the furnace are composed of silica brick and, in the larger furnaces, are incased in a sheet steel frame. Insulating material is placed between the silica brick and the casing.

The furnace base consists of a heavy cast-iron plate supported by cast-iron legs or brick piers.

The cable terminals are connected with the electrodes by means of iron sleeves, copper straps and iron wedges.

In making the connection the iron sleeve is placed over the end of the electrode and copper straps placed against the four sides of the electrode. The copper cable terminal is then placed between one of the copper strips and the iron sleeve, and wedges driven in on the opposite side between the strap and sleeve, and a firm contact thus secured. Wedges are then driven in on the other two sides between the copper strips and

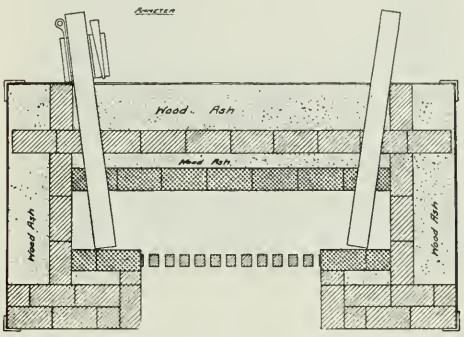

FIG. 3. HORIZONTAL SECTION.

the sleeve. In this way the current flow is equally distributed on all four sides of the electrode by means of the encircling iron sleeve.

The furnace is controlled by means of the regulating transformer and controller. The transformer gives full rated output at the lowest voltage rating. While hand regulation is usually provided the regulation may be made automatic at a slight additional cost. A voltage range of from 33 to 50 per cent is usually provided, depending on the operating and starting requirements.

The metal being heated is maintained in a reducing atmosphere, the high temperature carbon resistance material giving off a gas of a reducing nature. The electric furnace is the only furnace built in small units in which both a high temperature and a reducing atmosphere may be maintained. The saving in oxidation loss is very considerable in small furnaces of this character, as the loss from oxidation in the usual combustion furnace is the cause of the loss of a large number of forgings, due to the fact that a piece of stock, having lost a considerable amount of metal by the oxidizing flame of the combustion furnace, does not contain enough metal to fill the dies.

The thermal efficiency of the furnaces varies with the size, the percentage of operation at full capacity and the ruling temperature required. Efficiencies of from 33 to 65 per cent may be expected in furnaces with heating capacities of from 120 lb. (55 kg) per hour to 1000 lb. (455 kg) per hour.

In the concluding part of his paper Mr. Bailey gave details of a test of an experimental furnace at the plant of the Transue & Williams Company in Alliance, Ohio.

The principal advantages of this electric furnace are stated to be its high thermal efficiency, its non-oxidizing atmosphere in the furnace chamber at all temperatures, and its freedom from

soot, smoke and the hot contaminating gases of the products of combustion.

In the discussion of Mr. Bailey's paper Dr. Richards remarked that the efficiency of this furnace was high in view of the unfavorable conditions and that very effective use was made in this furnace as in Mr. FitzGerald's furnace (see abstract above) of the principle of getting the resistor hottest at the place of its radiating surface. Messrs. Hering, Sperry, Lidbury and Hitchcock also participated in the discussion.

As to the "efficiency" of an electric furnace, Dr. Richards proposed to define it as the ratio of the heat actually used for

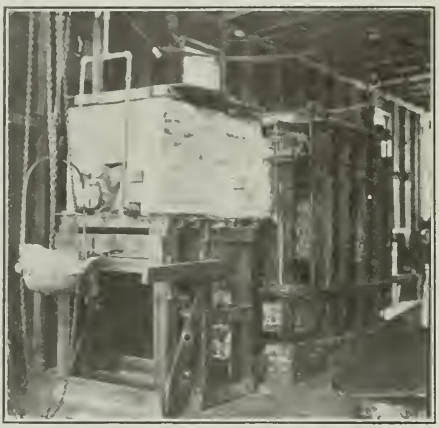

FIG. 1. ELECTRIC ZINC FURNACE.

useful purpose to the electric energy consumption. Mr. Lidbury did not like this definition, as according to it any furnace in which the temperature of the charge is not raised, for instance the Heroult steel furnace, would have zero efficiency.

In reply to a question of Mr. Hitchcock, Mr. Bailey stated that coke was usually added every five or six hours.

Electric Zinc Furnace.

Prof. Jos. W. Richards, of Lehigh University, then presented a paper on the Johnson electric zinc furnace. He stated that at the present time there is considerable interest among metallurgists in electric zinc smelting. This is an exceedingly gratifying circumstance to the American electrochemical world, as thirty years ago those electric furnace pioneers, the Cowles Brothers, tested out an electric furnace for smelting zinc ores from a New Mexican zinc-copper mine. As zinc smelters they were ahead of their time, but their interest in that zinc mine was one of the predisposing causes of the rise of the electrothermic industries during the last two decades of the last century.

If the zinc business once helped the electric furnace, certainly now the electric furnace can help the zinc business and repay its debt by giving it a continuous furnace of large capacity. For it is a commonplace remark in metallurgical circles that the process for making spelter has not been improved in principle since its birth, one hundred or more years ago. This is true in a measure and in a measure untrue. It is untrue in that hydraulic-pressed retorts and regenerative retort furnaces and mechanically operated calcining furnaces are advances. But it is true in that the same old retort averaging a charge of 50 lb. (23 kg) of roasted ore, with the costly and inefficient crude hand labor, with its limited life and its inability to stand corrosive ores, is still the operative unit. In the United States there are some 100,000 retorts making each 5000 lb. of metal per year.

Now, in this respect the electric zinc furnace which puts the heat right where it is needed and used, and so can be built in large sizes, is far ahead of the old retort potentially. Furthermore, a continuous character of operation is possible in electric smelting, and this is inherently better than the intermittent character of the present method of smelting of zinc ores.

It is quite within the bounds of probability to expect 500-kw zinc furnaces, each making 4000 tons of metal a year, the equivalent in production capacity of 1600 retorts.

The natural presumption is that when once developed to a practical and commercial basis the extraction of the main and by-product values will be greater in the twentieth century process than in the nineteenth century process. Likewise the labor charge per ton of ore will be far less, the metal purer and more uniform. The capacity for smelting a variety of ores will be greater, and the control of temperatures be better. The cost of electric power will approximately equal the cost of coal in the present practice.

Mr. W. McA. Johnson's first large-scale experimental work in the electrometallurgy of zinc was directed along lines of treating a charge that produced a dry fusible residue. Much actual progress was made in that line. Photographs of his earlier furnaces are shown in Figs. 1 and 2. He later concentrated his investigation on a proper practical condenser for large-scale continuous operation, which he considers to be the keystone of the "electric zinc" problem. For the last two years Mr. Johnson has been engaged in developing an electric fur-

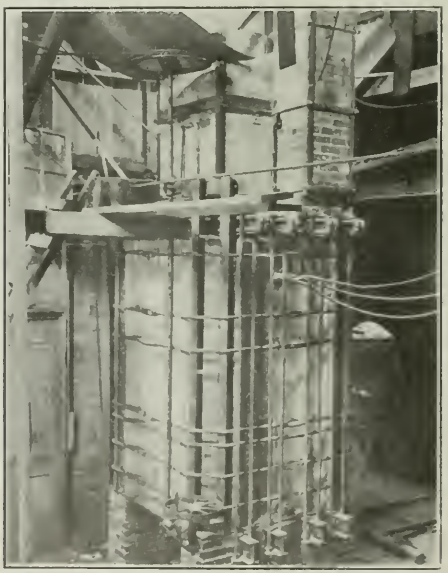

FIG. 2. ELECTRIC ZINC FURNACE.

nace to smelt zinc ores with the production of a base lead bullion, a copper-matte and a fusible slag. This is more difficult than the dry process, but far more attractive commercially. To use his own words "the smelting zone of my electric zinc furnace is practically a lead furnace, but operated by electrical heat and with slightly more intense reduction conditions, sufficient to reduce the zinc but not to reduce appreciable amounts of the iron oxide present in the slag."

The furnace (see also our Vol. VIII, p. 688, December, 1910) is of the Siemens arc type with certain important modifications.

In the smelting operations a certain percentage of carbon dioxide is evolved. This is fatal to efficient condensation. To reduce the percentage of blue-powder and dross to a minimum, or to ensure a high "condensation factor," i. e., a high percentage of metallic spelter made direct to total spelter made, Mr. Johnson passes his reduction gases through a filter of carbonaceous material. This reduces the percentage of carbon dioxide to extremely low limits, lower than those in the gases emanating from the ordinary retort. The condenser that Mr. Johnson uses in conjunction with this type of furnace is simple, yet designed to expose the vapor to the surface of metal, to abstract the heat and to regulate the temperature. Mr. Johnson's condensation factor averages usually somewhat higher than that in the ordinary retort plant. In usual practice from 70 per cent to 80 per cent of the spelter is made direct, and from 30 per cent to 20 per cent from the resmelting of "blue-powder" and furnace products.

Mr. Johnson's slag losses are remarkably low. Usually 99.5 per cent of the zinc content of the charge is reduced and volatilized, while 0.5 per cent of the zinc content passes off in the slag. The remarkable feature of the little 25-kw furnace which Dr. Richards had seen in operation is its great smelting capacity per unit of cubic content. The rate of reduction is about fifty times as fast as in the fireclay retort, and the rate of smelting about five times as fast as in the ordinary lead furnace. Furthermore, with proper manipulation the heat requirements of the charge are reduced to a minimum. Mr. Johnson is now engaged in working out his ideas on a much larger scale. If he is on the right track the ease of smelting and condensing will be greater in his commercially sized unit than in his 25-kw furnace. In the light of metallurgical experience an inventor is on the right track when on increasing the size of his operation his difficulties and annoyances decrease and conversely he is on the wrong track when on increasing the size of his operation his troubles increase.

Entirely irrespective of the merits and possibilities of Mr. Johnson's electric zinc smelting furnace, Dr. Richards believes that we shall see in the immediate future the start of the abolition of the fireclay retort, and that we now see the dawn of the new era of electric smelting in the zinc business.

Condensation of Zinc.

A paper by Mr. F. T. SNYDER, of the Metallurgic Engineering Company, of Chicago, dealt with the condensation of zinc vapor from electric furnaces. If the electric zinc furnace is successful, the design of large zinc condensers becomes of great importance. With electric zinc furnaces it is practical to deliver zinc vapor to a condenser at a rate 300 to 400 times the rate at which such gases reach the standard retort condenser. It is at once evident that the trade-skill basis of design is inadequate and that the opportunity exists for the application of engineering methods to the design of zinc condensers.

Mr. Snyder bases his discussion on the well-known data of the design of the successful small zinc retort condenser and shows how to derive therefrom data for the design of larger condensers. He analyzes in great detail the conditions of temperature and pressure and the phenomena of zinc condensation in the ordinary retort condenser. From these he reaches the following chief conclusions for use in the engineering design of larger condensers.

If we provide 1 sq. cm of clay cooling surface (or an equivalent amount of some other material) for each 0.40 gr. of zinc to be condensed per hour, and if we arrange the thickness of the material of this surface and the temperature conditions at the other or non-condensing side of the material so that 0.21 kg calories of heat will flow through each sq. cm of the surface per hour when the average temperature of the condensing surface is 725° and if we arrange the volume inside the condenser, so that the product of the average longitudinal velocity of the gases in cm per second and the average diffusion distance (corrected to the standard temperature of 864°) in cm, through which the zinc has to diffuse, is 9.5, then, the design of the large condenser will be on the same basis as the proportions of the standard retort condenser. It is to be kept in mind that only the cooling surface in the condenser that is between 850° and 450° counts in the production of liquid zinc. As this upper limit of 850° depends on the atmospheric pressure, the reduction of the atmospheric pressure with high altitude is to be taken into account for a condenser so located. It is interesting to note in the standard retort condenser, the proportions of which have been determined by many years of "cut and try," that these proportions now in general use give a diffusion factor that is substantially constant throughout the length of the condenser. This means that these proportions represent the maximum commercial economy in the use of the condenser material.

As to further details reference must be made to the full paper, which will be printed in full in the *Transactions*.

The author finally examines the design of one of the large condensers which have formerly been built—that in connection with the Lynen furnace—and shows in what respect this design was deficient.

In the discussion which followed this paper, Mr. Hansen stated that in a continuous run with the Weeks electric zinc furnace at the General Electric Company's plant in Schenectady 1600 lb. of zinc had been successfully and very satisfactorily condensed. Messrs. Bleecker and Quenean also participated in the discussion. In reply to a question of the latter, Dr. Richards stated that the specific yield of Johnson's furnace is 2 tons of zinc per horse-power-year; which is better than at the DeLaval plant in Trollhattan.

Reliability of Electric Furnaces.

Another paper by Mr. F. T. SNYDER dealt with the reliability of electric furnaces for commercial work. This paper had previously been presented before the Chicago section of the society. The conclusions are summed up as follows:

The electric furnace itself has passed from the field of experiment to that of engineering, but the fields of manufacture using the electric furnace products are still experimental.

The electric furnace is technically reliable and will operate continuously with the men and supplies that are available in this country. The details are simple and rugged, and the inherent regulating powers can be made such as to bring it well within the ability of usual plant labor.

The electric furnace is commercially reliable. When installed with the same business care and adaptation to conditions that should be used with other furnaces it will earn a profit on the investment, and a profit that is larger than the normal manufacturing profit in proportion as the field is newer and more open.

Incidentally Mr. Snyder mentioned that he recently examined an electric furnace plant, which started operation on a commercial scale in the summer of 1907 and which is now to be increased fivefold. Substantially all of the original equipment is still in use. The plant, which is in the West, has been operated since its installation by Chinese labor under a white superintendent and neither the superintendent nor the Chinamen know more of electricity than is involved in the opening and closing of circuit-breakers and the reading of ammeters and voltmeters. This particular plant, while not a steel plant, is of interest in showing on many of its operating records a heat development efficiency of over 90 per cent. That is, of the heat equivalent of the energy delivered to the plant by the high-potential electric wires, over 90 per cent is transferred to the material under treatment.

The paper was discussed by Dr. Amberg and Mr. Fitzgerald. The latter referred to the claim of a 90 per cent efficiency and said that as the loss of energy in the transformers, which presumably are used in connection with the high-potential wires, must amount to about 3 per cent, there is left only 7 per cent for the losses by radiation and the various other losses inevitably

associated with work of this kind. "It is not intended to deny the accuracy of Mr. Snyder's statement, but merely to point out that such an extraordinary observation should be at least substantiated with an account of the methods used in arriving at the result."

The Cyanamide Process for Gold.

The first paper called for discussion in the session of Friday morning was the paper of Mr. John Collins Clancy, of the Moore Filter Company, of New York City, on the electrolytic cyanamide process for treating gold ores which was presented before the New York section of the society some time ago and which was published in full in our January issue, page 21. It was discussed by Dr. N. S. Keith and Dr. A W. Smith.

Dr. Keith gave some principles of the ordinary cyanide process with special reference to Elsner's equation $4Au + 8 KCN + O_2 + 2H_2O = 4KAu(CN_2) + 4 KOH$, to show why and for what purpose the free oxygen is needed in the process, and described some simple experiments demonstrating some of the reactions in the cyanide process. He then criticized rather severely several points in Mr. Clancy's paper, especially the use of the term "protective alkalinity," further the proposed employment of cone-shaped tanks supplemented by blankets for separating sulphides from the gangue accompanying them in the pulp. He also thinks that the solvent of Mr. Clancy is rather complex and that the use of the electric current for regeneration of the solvent is too expensive.

Mr. Clancy's reply will be printed in the *Transactions* of the Society.

Electrolytic Amalgamation.

A paper by Mr. Elmer Ellsworth Carey dealt with "the electrolytic system of amalgamating gold ores." He pointed out the difficulties of ores where crystals of iron pyrites are found in quartz, and within the pyritic crystals are gold particles in a finely divided state. The values in such crystals cannot be recovered on the usual mill plate, as the particles of gold are coated with various substances, preventing amalgamation. The present practice is to separate the pyritic crystals from the crushed ore by various types of concentrating tables. This so-called concentrate is then sent to a smelter, or it is ground in tube mills (100-200 mesh) and delivered to the cyanide tank, where the extraction ranges from 85 to 96 per cent.

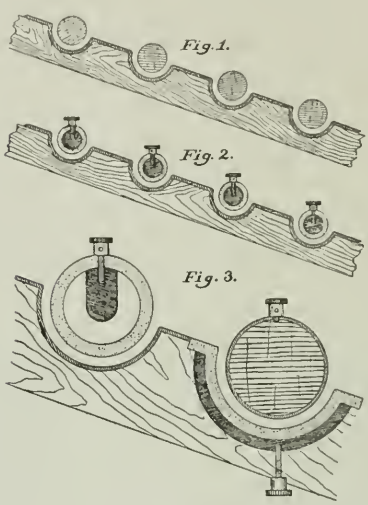
For these treatments Mr. Carey proposes to substitute fine grinding (100 mesh) and electro-amalgamation. An ideal plant for this process consists of some type of rotary crusher, with outside screening, possibly a secondary crushing device to finish the work of the first crusher, and from the crusher the pulp, ground sufficiently fine to release all economic values, is passed over electrolytic amalgamating devices. The released values are recovered in the form of amalgam.

In electrolytic amalgamation, the sole function of the electric current is to deposit hydrogen, sodium, potassium or ammonia in the mercury. The sole function of sodium or potassium is to deoxidize water, and the final work in the chain of reactions is the liberation of nascent hydrogen at the surface of the mercury. As the particles of gold sweep over the electrolytically excited mercurial surface, all substances usually preventing amalgamation are automatically and almost instantly destroyed or rendered inert. Grease is saponified by the caustic soda; oxide coating on gold particles is reduced by hydrogen; in a word, gold particles are cleaned and amalgamation quickly follows.

Hungarian mercury wells are described in Vol. II of Prof. R. H. Richards' Work on Ore Dressing; by making the baffle in such wells an anode, using suitable material, and employing an 8 to 12-volt current of high amperage, we have an electrolytic amalgamating device. The objections to the use of such mercury wells disappear when they are electrified, and their extraction efficiency is greatly increased. The interior of such wells must be lined with some very refractory substances.

A simple experiment showing the activity of hydrogen-sodium amalgam and the value of electrolytic amalgamation is to place a piece of plastic sodium amalgam of the size of a pea in a test tube, to add an ounce of water heavily saturated with ammonium chloride, and to test the amalgamating powers of the very curious resultant amalgam by copper and iron wire.

The amalgamator for gold ores consists of a series of electrolytic sodium-mercury cells, followed by another electrolytic amalgamating device in which the values are recovered on silver-plated copper plates of suitable construction. With the mercury wells high amperage may be employed, liberating large volumes of hydrogen, which removes all coatings (oxides, sulphides, grease, talc, silicious coatings, etc.) from the micro-



FIGS. 1, 2, 3. ELECTROLYTIC AMALGAMATION APPARATUS.

scopic gold particles; in the secondary amalgamator the plates offer a large cathode area so that all portions of the pulp are forced into contact with a highly active mercury surface. The supplementary amalgamating device above mentioned consists of a silvered copper plate of suitable width; this plate contains parallel, transverse, semi-cylindrical depressions (grooves, pockets or riffles) the full width of the plate; into these grooves project cylindrical terra cotta cylinders, leaving a ¼-in. clearance, from 3 to 4 in. in diameter; these cylinders contain a graphite core, 1 in. in diameter, connected as an anode.

The pulp passes under the cylinders, and sweeps gently over the curved (cathode) amalgam plate, while gravity, the force of the water and centrifugal force tend to drag each gold particle into contact with the highly excited mercury surface.

Fig. 1 shows a section of a new type of mill plate which Mr. Carey has devised. The sides are not represented. The silver-plated copper plate (being of the usual length of amalgamating plates) contains transverse parallel semi-cylindrical grooves into which fit solid cylindrical wooden baffles; these baffles may also be made of standard piping or casing, from 3 to 4 in. in diameter, with the ends closed. The clearance between the plates and the baffles is from 3/16 to ¼ in. One piece of copper plate may be used, with the proper depressions pressed therein, or, preferably, a number of overlapping plates may be used, each plate containing one or two semi-cylindrical depressions. The plates are held in position by their own weight, fitting closely to the sides, and can be quickly removed from the device for cleaning up. The device may be given any desired grade, and the plates are dressed and operated as the usual mill plate. A mill plate arranged as described will make a

better extraction on the average ore than the usual type of amalgam plate, there being no loss of amalgam.

In Fig. 2 is illustrated an electrolytic mill plate, constructed similarly to the one shown in Fig. 1, which will not only recover all values saved by the standard types, but in addition all free values in silicious pulp and slimes, all values in placer material, beach-sand and all black-sand values are also recovered. The cylindrical baffles are made of terra cotta, and each contains a graphite core connected to the positive lead of a low-voltage generator; the amalgam plates are connected to the negative lead of the generator.

In the first groove or riffle shown in Fig. 3 the water and pulp pass over the amalgam plates as in Fig. 2; in the second riffle of Fig. 3, the amalgam plate connected to the negative lead forms a casing for the baffle, and the pulp stream passes under the mercurial surface, thus bringing the surface of the water into intimate contact with the electrically excited mercurial surface; or a copper cylinder, silver plated, may be used as a baffle, and at the same time act as an amalgamating surface.

A gold-saving device may consist of a series of such riffles as are shown in Fig. 3, arranged alternately; such an arrangement is particularly useful in treating pulp containing gold in a finely divided form, or for recovering values in slimes or in solutions. By screening placer material to 10 or 12 mesh, and passing the undersize of electrolytic amalgamating sluiceway of suitable length, all fine, rusty, float, coated, and greasy gold is recovered.

In certain classes of base ores it may be necessary as a preliminary measure to treat the pulp for 30 minutes by electrolytic pan amalgamation before passing the pulp over the electric sluice; and for ores containing gold in chemical combinations (sulphotellurides, etc.) a preliminary roasting may be required.

In the discussion of Mr. Carey's paper, Dr. Keith said that, while the idea of electrolytic amalgamation was old, Mr. Carey had improved on the apparatus.

Electrolytic Corrosion of Electroplated Objects.

A paper by Prof. Walter S. Landis, of Lehigh University, referred to the observation that gold-plated steel pens corroded far more rapidly than plain steel pens. This is due to the fact that the friction of the pen point on the paper rapidly wears off the plating on the point, thus exposing the steel; an electrolytic couple consisting of steel, ink, and gold is thus set up and corrosion results.

The e.m.f. of the couple was measured between a fresh gold-plated pen and a like pen, stripped of its gold plating, in different kinds of ink.

"While the corrosion of the plated pens is not a matter of great commercial importance, yet there is to be gained from the experience a certain wholesome lesson on the application of electroplating to the protection of less noble metals: Do not plate with a nobler metal a material that is likely to be subjected to wear on one spot and which spot is to be moistened with liquids. For, as soon as the plating is worn through on that spot, accelerated corrosion will take place, and in the end the resulting corrosion will be far worse than without the plating."

The paper was discussed at some length by Messrs. Murphy, Walker, Hering, Richards, Hogaboom, Kohn, and Willard. The latter pointed out that nickel-plated iron or steel will invariably rust in a moist atmosphere. Not only the weight of the nickel deposit, but also its continuity are of primary importance, and it seems impossible to insure absolutely the latter in commercial practice.

Electrolytic Iron Refining.

A paper of Prof. Charles F. Burgess, of the University of Wisconsin, which had already been presented before the Chicago section of the society, dealt with electrolytic refining as a step in the production of steel. The question is: Can iron, refined electrolytically by his process (our Vol. II, page 183), be made an industrial product? Iron can be refined electrolytically almost as easily as can copper. Whether there is a field of usefulness for such iron depends upon whether electrolytic iron has superior qualities due to purity or physical condition, and whether it can be procured at low cost.

From the standpoint of purity it must compete with some notable metallurgical developments which have resulted in the product such as is being made by the American Rolling Mill Company in a basic open-hearth process. The electric furnace is another factor which is contributing largely to the control of the composition and purity of iron alloys.

The chief source of commercially pure iron has been, and perhaps now is, the high grade Swedish and Norway iron, used largely as a base material for high-grade crucible steel. The analyses of this material usually indicate a high purity, though frequently and erroneously calculated by difference after determining carbon, sulphur, silicon, phosphorus and manganese. It is not uncommon to find oxides and slag to the extent of 2 per cent in this material, and this impurity undoubtedly may have an influence on the resulting alloys made from it.

Electrolytic iron can be produced with a purity as high as 99.97 per cent and perhaps even better, using extraordinary precautions. This record has been made by using the best commercial grades of pure iron as anodes. A few hundredths of a per cent of purity must be sacrificed in using anodes of mild steel or other less pure materials. Further the uniformity of this electrolytic iron should be of importance for its uses.

Using an electrolyte containing 40 grams of iron per liter in the form of ferrous sulphate together with 40 grams of ammonium chloride, it has been found possible to conduct a continuous refining operation for many months at a current density of 6 amp to 10 amp per square foot of cathode surface, and at a potential difference of about 1 volt. The current efficiency is very close to 100 per cent, as it is in copper refining.

This leads to the calculation that 1 kw-hour will refine 2 lb. of iron; or a cost for power of ½ cent per pound is attainable. The costs for labor, solution maintenance and fixed charges are estimated to be not greater than the power costs, making a cost of refining of about $20 per ton. Assuming the anode material to be mild steel costing $35 per ton, the cost of electrolytic iron would be in the neighborhood of $55. These approximate calculations indicate that this material might well compete in price with high-grade Swedish iron.

Among the properties of electrolytic iron which may give it some added usefulness is its content of hydrogen and the brittleness which results from this occluded gas. This hydrogen may be of some service in reducing oxides in a melt. The brittlenes of the electrolytic iron before the hydrogen is driven off makes it easy to break it up into pieces suitable for introduction into the steel crucibles.

Unsolved Problems in Electroplating.

A paper entitled "Some Unsolved Problems in Electroplating" was presented by Mr. George V. Hogaboom, secretary of the National Electroplaters' Association. He pointed out that electroplating has been looked upon more as a trade than a science, and that its development has been left to the practical man, guided only by "rule of thumb." An electrochemist in the plating room of a factory is so rare that it probably can be said without fear of contradiction that they can be counted on the fingers of one's hands. The need to-day is mutual co-operation between scientific electrochemists and practical platers in solving their problems and developing new ideas.

In the discussion of electroplating problems, it must be borne in mind that a mere deposit of a metal is not all, but that the deposit must be soft and smooth and lend itself to a decorative process; the anodes should be capable of being reduced easily; the electrolyte must offer little resistance to the electric current,

and, last, but not least to the plater, who hears it so often that it becomes a part of him, the cost must be nominal.

The automobile industry has brought about, more than anything else, the need of a heavy deposit of brass. At present this is done in a solution of cyanide of copper. The deposit is not only slow, but unsatisfactory, because of what is known as "spotting out"—a discoloration in spots which appears on the work after it has been polished and lacquered. Deposits on cast metal give the most trouble It is probably caused by the acids or alkaline solutions being absorbed in the pores of the metal, or in the small blow-holes, and the deposit covering these holes partially, leaving minute holes through which the solution oozes out. Several remedies have been suggested and tried, such as boiling out in some neutralizing chemical solution, placing in a drying oven for several days, but a satisfactory remedy has not been found.

An acid brass solution would be a great advantage. There is an acid copper and an acid zinc solution, but no acid brass electrolyte. The difference between the deposit from a cyanide and a sulphate of copper solution well illustrates the advantage of having an acid brass solution.

Tin.—The formula for a tin solution published by Roseleur is the most generally used to-day, as little, if any, improvement has been made upon it, although a good solution which would give a heavy deposit is much desired. In Roseleur's solution the electrolyte is not replenished by the anode, but by the constant addition of a concentrated solution. This should be overcome, and would be appreciated by manufacturers of tinware.

Aluminium.—While several solutions have appeared from time to time for plating upon this metal, none of them are in general use, and a good electrolyte that would deposit gold, silver, brass or copper so that it would stand burnishing and not peel off in time could be used.

Nickel.—The successful removal of a deposit of nickel from another metal without affecting the latter has not been accomplished.

To give all the unsolved problems in detail would make a lenghthy paper, and a simple statement of those most desired will be given:

An electrolyte that will remove the fire-scale from brass: also one that will produce a bright or a matte surface in place of using the present acid dips.

An electric cleaner that will saponify the grease and take it into solution instead of driving it to the top, where it has to be constantly removed to prevent it adhering again to the work as the latter is removed from the solution.

A heavy deposit of lead on the inside of iron pipes, to prevent rapid corrosion.

A method to coat electrogalvanized iron or steel with decorative metals without destroying the rust-resisting properties of the zinc.

An alkaline nickel-silver solution that can be worked with a low voltage.

A method of etching steel without destroying a resistance film of gelatine.

Some alkaline substance that would replace cyanide of potassium. This would be universally welcomed.

For the above suggestions the writer is indebted to 100 different platers, who were kind enough to answer a request for unsolved problems. It may be interesting to note that 80 per cent of them requested an acid brass solution.

In the discussion Mr. Lidbury said that the list of unsolved problems was quite interesting but that it would seem that at least half the problems were easy of solution, if electroplating shops would employ competent electrochemists. Dr. Walker said that in their jealous secretiveness many modern electroplaters (and some other manufacturers) compared with the old alchemists, but that progress depends on the free interchange of ideas.

Polarization.

A paper by Dr. Oliver P. Watts, of the University of Wisconsin dealt with polarization in the relation to the decomposition pressure of electrolytes. Dr. Watts endeavored to show that the principal factor in causing the phenomenon of the decomposition voltage as observed in electrolysis is not the resistance of a gas or other film upon either or both electrodes, but that it is due to a counter e.m.f. which is produced at the electrodes as a result of the action of the impressed e.m.f. This counter e.m.f. is referred to as polarization.

By the introduction of a third electrode and the measurement of the differences of potential between this and the anode and cathode, it is possible to ascertain what proportion of the total polarization is contributed by the anode and what by the cathode. The most satisfactory reference electrode to use for this purpose is the normal calomel electrode. The results of various tests are given in which the total polarization as well as the anodic and cathodic polarizations separately were determined.

The source of the counter e.m.f. is of the same nature as the e.m.f. of any primary or storage cell, viz., it is the result of an unsymmetrical electrochemical system, consisting of two electrodes in one or more electrolytes. Before electrolysis the electrolytic cell was symmetrical consisting of like electrodes in an electrolyte of uniform composition, concentration and temperature, and therefore the e.m.f. of the cell was zero. With copper sulphate and platinum electrodes the application of an e.m.f. causes the system to become unsymmetrical, by the deposition of copper at the cathode and oxygen at the anode. The e.m.f. of this little copper-oxygen storage cell, which, as in all storage cells, is opposite in direction to the charging e.m.f., continues to increase in magnitude, as more and more copper and oxygen are deposited, until its e.m.f. equals the impressed e.m.f., when the flow of current ceases. All this may occupy one or two seconds. With each increase of impressed e.m.f. this process is repeated, until the value of the impressed e.m.f exceeds that attainable by the little storage cell; then a permanent current flows.

This refers to insoluble electrodes. With soluble electrodes the concentrations of the electrolyte are changed right at the electrodes and this change of concentrations produces a counter e.m.f.

The final conclusions of Dr. Watts' paper are as follows:

Polarization is responsible for the phenomenon of decomposition pressure in electrolytes.

The total polarization may be resolved into two components, the one at the anode, the other at the cathode.

Since it is polarization which prevents the flow of current in accordance with Ohm's law, the residual current is the equivalent in current of the rate of depolarization of the electrodes by the electrolyte

Moreover, if electrolysis causes a change in the material of an electrode, or of the electrolyte in immediate contact with it, the polarization at the electrode is large. This is the case with an insoluble anode, and usually so for a cathode whose position in the electrochemical series is far from that of the element which is deposited upon it by the current.

If the chemical composition of the electrode and of the electrolyte in contact with it are not changed, the polarization will be small. This occurs with a soluble anode and with a cathode of the same material as that deposited by the current.

The paper was briefly discussed by Mr. Hering and Dr. Richards.

Electrical Heating as a Means of Prevention of Superheating.

A paper by Dr. J. Howard Mathews, of the University of Wisconsin, described a modification of the method proposed a number of years ago by Bigelow for the determination of molecular weights in solution by elevation of the boiling point.

The modification consists primarily in the arrangement of the heating spiral, in the use of a heavier heating current and in the more accurate control of the heat thus supplied. With the apparatus as described, and with the precautions enumerated, it was found possible to make molecular weight determinations with a degree of accuracy heretofore unattainable. The use of glass bead in the boiling chamber has not only been shown to be useless as a means of prevention of superheating, but is a positive detriment.

A long series of determinations were then made to ascertain whether the slight superheating effect experienced would be the same when wires of different materials were used for the heating elements. It was shown that German silver wire produces a much greater degree of superheating than any of the other wires used. Wires of the resistance materials known as nichrome, advance, manganin, and monel showed but little tendency to superheat. The tendency to superheat the liquid was not found to be dependent in any way upon the specific resistance of the heating element. German silver wire when rolled out in the form of a ribbon and well roughened with a file showed about as little tendency to superheat the liquid as did wires of platinum or of the other materials above enumerated. A covering of oxide over the surface of a smooth German silver wire seemed to produce no effect upon the tendency to superheat.

Bifunctional Accumulator.

Mr. A. O. Tate, of Toronto, Ont., Canada, then presented a paper on his new "bifunctional accumulator." Nothing is changed in the chemistry of the ordinary lead accumulator. Mr. Tate's work has been chiefly along mechanical lines. The positive and the negative elements are contained in the same plate on both sides of it, hence the name "bifunctional." The chief mechanical feature is the use of short narrow conducting strips, separated by perforated celluloid strips. The slight depth of the active material permits very quick charging. Other claims for the battery are very uniform current density, insurance of good contact between active material and support, and avoidance of sulphating.

In reply to a question by Dr. Brown, Mr. Tate stated that the battery gives 11 to 12 watt hours per pound of complete battery in service.

Production of Aluminium in Laboratory.

Dr. H. K. Richardson, of the Pennsylvania State College, presented a paper on "Some Observations on the Laboratory Production of Aluminium." The paper gave an account of runs made by students during the regular scheduled laboratory periods in electrolytic deposition of aluminium. The author follows in many respects the method of Neumann and Olsen (this journal, Vol. VIII, p. 185).

The instructions given to the students are as follows:

Make 4 kg. of a mixture:

Alumina .....20 to 15%

Natural cryolite .....80 to 85% old charge

Melt up 3 kg. of charge at once. Add the remainder as the bath becomes diminished.

Remove the heating carbon as soon as the bath is thoroughly fluid.

Add alumina to bath every 30 minutes. Quantity to be calculated on assumption of 50 per cent current efficiency.

Use anodic current density of 3 amperes per square centimeter.

If anode effect causes trouble, *i. e.*, current suddenly drops

(1) Open and close circuit quickly

(2) Add a charge of alumina

(3) Tap electrode sharply

(4) If none above effective, try adding cryolite.

If voltage gradually rises at constant current, add, in order named, alumina, mixture, or cryolite, whichever brings the voltage down.

Keep crust broken on at least one side of electrode. Crushed coke around the electrode will tend to keep crust soft.

Take voltage and current readings every five minutes.

The results of the tests given in the paper show that a satisfactory laboratory run can be made upon aluminium, following instructions as given above. The best results are to be expected under the following conditions:

Mix: 85 per cent natural cryolite; 15 per cent alumina.

Current Density: Approximately 3 amperes per sq. cm. of anode surface.

The anode effect appears to consist of two kinds:

(a) Gaseous envelope which opens the circuit. This can be remedied by opening and closing the circuit or tapping the electrode.

(b) Non-wetting of the electrode, thereby causing numerous small arcs to form from electrode to electrolyte. This causes the voltage necessary to be increased, and appears to be remedied by addition of alumina or cryolite, although it is present in some degree during the entire run.

In the hands of students, using the apparatus of the author, and following the instructions as closely as students usually do, an ampere efficiency of about 60 to 70 per cent may be expected.

Dr. Richardson's paper brought out quite an extended discussion. Dr. Jos. W. Richards stated that the value of 2.8 volts, given in the paper as the decomposition voltage, refers to the decomposition of the alumina, but the cell is to be credited with the voltage due to the oxidation of the carbon. Thus the theoretical voltage comes out as 2.25 volts. This agrees with practical experience. The energy efficiency of Dr. Richardson's tests is then less than 26 per cent. This agrees with the energy efficiency in practice, where it is 25 per cent. 75 per cent of the energy is consumed in keeping the bath at the right temperature. This fact emphasizes the importance of reducing heat conduction and radiation losses.

Dr. Richardson further pointed out that a high current efficiency of over 90 per cent is possible only with low temperatures. In practice a current efficiency between 75 and 80 per cent is attained, so that there is a loss of 25 to 20 per cent due to redissolving of aluminium in the fused bath.

Mr. A. H. Cowles doubted whether there is a redissolving of aluminium, except when there is a voltatic couple formed by the carbon walls and the aluminium.

Dr. Richardson replied that the dissolving of the aluminium was not due to a voltatic couple, but was a case of simple solution. Whenever a fused salt is electrolyzed there is a tendency for the metal set free to dissolve back into the fused bath, and this tendency is the greater the higher the temperature. If it was possible to work with the aluminium bath near the freezing point of aluminium, nearly 100 per cent efficiency could be obtained. But there is a practical reason, due to specific gravities, which prevents this. If the salt is cooled near to the melting point the aluminium floats on the bath.

There was some further discussion, especially on the analogous case of sodium, in which Mr. Cowles, Dr. Walker and Mr. Lidbury participated.

Electrolytic Meter.

A paper by Prof. Frank C. Mathers and Albert F. O. Germann, of the University of Indiana, dealt with a mercurous perchlorate electrolytic meter. Silver and copper are the metals generally deposited in coulometers or voltameters, but mercury has two great advantages for this purpose: it is liquid and has a very high electrochemical equivalent. The difficulty seems to have been in the past with the electrolyte to be employed.

The authors recommend very strongly mercurous perchlorate and give an account of their experiments with this electrolyte. They describe the preparation of the materials, conductivity experiments, and coulometer experiments, and sum up their results as follows:

The advantages of mercurous perchlorate solution as an electrolyte for meters and coulometers are:

The ClO_4 radical is exceptionally stable and is absolutely unchanged by electrolysis.

Mercurous perchlorate is very soluble in water, and the solutions thus formed are entirely free from any decomposition.

Mercurous perchlorate solutions containing free perchloric acid have very high conductivity, such that a very high current density may be used in electrolysis.

The amount of mercury deposited may be very rapidly determined by measurement rather than by the much slower method of weighing.

The deposited metal is in such form that it may be transferred to the anode for further use without any treatment whatever.

Equivalent quantities of electricity deposit from two to six times greater weight of mercury(ous) than of the other metals. This gives greater accuracy.

The paper was discussed by Mr. Schluederberg, who spoke of the reasons which have restricted the use of electrolytic meters in commercial practice. In this country they are not used at all, but in Europe to a certain extent in small direct-current installations, their chief advantage for small installations being their cheapness. Mr. Hering and Dr. Sharp also participated in the discussion.

Electric Discharge Through Gases.

Dr. Louis A. Parsons, of Johns Hopkins University, presented a paper giving an interesting and concise summary of the experimental work which has been done during the last few years by many experimenters on electric discharges in gases at reduced pressure.

He described the phenomena which have been experimentally established, and summarized the conclusions which can be drawn from the experimental evidence on the nature of electricity and matter and especially on the fundamental units of negative and positive electricity.

The paper was discussed by Dr. Whitney and Dr. Walker, who emphasized how much could be done by research work in universities and colleges along scientific lines.

Electrolytic Transfer.

A paper by Prof. Jos. W. Richards, of Lehigh University, discussed the mechanism of electrolytic transfer with special reference to the phenomena in fused salts. The author emphasized the frequent deviations of a chemical compound from the simple or fixed atomic proportions. For instance, if iron pyrites FeS_2 is melted, sulphur leaves it and at a low temperature one has Fe_4S_5, Fe_5S_6, Fe_7S_8, or various approximations to FeS.

By an increase of temperature one passes by insensible gradations all the way to Fe_2S, and at electric furnace temperatures perhaps beyond this.

A chemical compound in absolutely atomic weight proportions is practically unknown in the whole class of melted mattes. In general a rather extensive study of fused salts and compounds leads him to regard fixed atomic weight prooprtions as the exception rather than the rule, in practical work.

If a tube full of smelted PbS is electrolyzed, lead is set free at one end and sulphur at the other. Now, Dr. Richards argues, the deficit of lead at the cathode is quickly distributed by diffusion throughout the whole electrolyte, while the deficit of sulphur at the anode is similarly rapidly distributed throughout the electrolyte. This distribution of the two deficits at the two electrodes is made possible by the known solubility of such intermediate products in the normal salt, and amounts to a virtual transfer of the two constituents from the whole mass of the electrolyte to the electrodes.

According to this view, the transfer in electrolysis is essentially solubility and diffusion of these slightly abnormal compounds formed by electrochemical action at the two electrodes. Dr. Richards therefore claims that the electrolytic transfer occurs as the result of electrolysis and is not the preexisting mechanism of electrolysis.

In the discussion which followed Dr. Parsons suggested that to investigate the nature and mechanism of electricity one should begin with the simplest case, the transfer of electricity through gases, where the phenomena are already complicated enough, although much less in solutions.

Presidential Address.

In the evening of Friday a joint session with the New York section of the American Chemical Society was held, at which the retiring president, Dr. William H. Walker, of the Massachusetts Institute of Technology, presented his address on "Chemical Research and Industrial Progress."

Within the last few years research has become a word to conjure with. The new field of human endeavor epitomized by the word research represents a change in the method of finding truth rather than the intensity of desire to know the truth. It is understood now that a search for truth can only reach its goal through intimate contact with the things themselves, and an accurate determination of the facts concerning them.

In former ages the dictum of Aristotle that "industrial work

W. H. WALKER, RETIRING PRESIDENT AMERICAN ELECTROCHEMICAL SOCIETY.

tends to lower the standard of thought" prevailed, and it is to this want of sympathy that we must ascribe the fact that the old historians failed to note the discovery of even the most important early chemical processes, while they gave detailed accounts of those men who advanced mere speculations and taught untenable opinions on the constitution of the universe.

To find the philosopher's stone was the goal of the alchemists; their labors were not a search for the truth, but for gold. It may be a long step from the work of the alchemists to modern industry. But there may be something in common between the work of the ancient investigators and their influence on civilization, and chemical research of to-day and industrial progress.

The alchemists did not make material progress in their methods in centuries. The explanation of this is to be found in the secrecy which they at all times maintained. There was no accumulation of knowledge or experience and each succeeding investigator continued to grope around in darkness.

The change came in the thirteenth century with Roger Bacon who, in his treatise, showed that phenomena which had been attributed to supernatural agencies were in fact due to common and natural causes. He is to be regarded as the intellectual originator of experimental research. Just as knowledge was sought after for its own sake, and in proportion as there was free and honest intercourse among the investigators of the time, just so rapidly was real progress made.

But for many years after the broad generalizations upon which modern chemistry is founded were well established industry did not profit much by scientific work. One hundred years ago the men who melted the iron and copper, the lead and zinc knew little of the principles underlying their practice. Leather was tanned, woolens, cottons and silks were dyed, porcelain and glass were made without the aid of those who alone knew the chemistry involved.

It is not that scientific men took no interest in the manufacturing industries, for we can recall the great work of Liebig for agriculture, and the immense amount of analytical chemistry which is the foundation of industrial chemical practice, but these were times when the advance in chemical knowledge was far ahead of the industries on the success of which our material comforts depend.

A real attempt to apply chemical knowledge and methods commenced about 1850. It was in 1856 that Perkins made the first synthesis of a coal-tar color, and founded the industry which has become the most remarkable example of applied chemistry that we have. In 1855 Bessemer introduced his revolutionary process for making steel, made possible by the clear understanding of the nature of steel through improved analytical processes.

The last fifty years may be said to be characterized by the production of men who combined the ability to appreciate and enjoy work in science for itself alone, but also possessed the ability and inclination to apply their chemical knowledge and training, and to make results of past generations of pure scientists of ever increasing service to humanity.

But within the last ten or fifteen years we have seen a third kind of chemical activity develop, namely, a class of men who while possessed of the ability and love of science which characterized the leaders in pure science of old, yet are not handicapped by the doctrine of Aristotle that contact with industry contaminates thought. This movement is seen in the tendency of great industrial organizations to establish research laboratories within themselves, and in the willingness of educational institutions to maintain research work in these fields of chemistry which are immediately applicable for industrial practice.

For the purpose of further studying the relationship existing between chemical research and industrial progress, Dr. Walker divided this kind of chemical activity into three classes. First, there is that which for want of a better term we will call original work in pure chemistry; second, there is the work of the so-called industrial chemist, the man who primarily applies existing chemical knowledge to the accomplishment of specific ends, and third, there is research work in what again for want of a better name he calls applied chemistry.

The environment of pure science has in the past been academic; the great investigators were teachers. This is so in America as in Europe. But there is a very different attitude shown toward men of science here and in Germany, for example.

In Germany everybody trusts science, even the Government. The Germans are accustomed to consult a scientific expert before going into a new business. That is the reason why; as Oswald says, Germany has managed to put more brains into her goods and has assumed its present position in the world.

Our American industries have flourished very well, it is true, but rather in spite of a lack of scientific aid, than on account of such aid. We have grown vastly satisfied with our achievement, but we might pause now in our self-congratulation long enough to inquire whether the things we are doing cannot be better done.

There is a mutual obligation existing between our educational institutions and our industries. The former must continue to increase their facilities for the research, which has made the German universities the avenues through which German civilization and industry have been brought to the point that we find them to-day.

On the other hand, the industries should not fail to recognize that progress based alone on industrial prosperity is but apparent progress, and that a sound civilization depends not only on conditions which make for material comfort, but on the culture which comes from an education in the broad sense that scientific research implies.

The great tendency of our times is toward service. This is seen in every sphere of human activity.

There is with scientific men a general awakening to the fact that the highest destiny of science is not to accumulate the truths of nature in a form that no one else but the select few can utilize, but that the search for truth can be combined with a judicious attempt to make the truth serve the public good. Thus the distinction which has existed between the terms pure science and applied science is rapidly falling away. An attempt to define these two kinds of science reveals the fact that this distinction is a general impression rather than a clear statement.

According to a fundamental law of psychology thought tends to pass over into action. Applied science is nothing more than the realization of this, and is thought in action. Force does work only when in motion, so are ideas of value only when carried into effect.

But the carrying of an idea into practice is not always an easy matter. It is frequently much easier to make a discovery or to develop a new fact than it is to make of such a discovery a serviceable reality. For example, the reactions underlying the ammonia-soda process were well known as scientific facts for many years, but this knowledge did not benefit the world until the genius of Solvay made through it purer and cheaper soda available. Cavendish long ago discovered that an electric spark produced nitric acid in the air, the world waited until but a few years ago in order to profit by his knowledge. It was then that the researches of Birkeland and Eyde made of the idea an industrial process.

Men who can interpret the scientific results already available have been of incalculable value in the growth of our industries, and there will ever be a field for this type of chemical activity. In fact it is just here that we find the faith of the Germans in science bearing fruit. In America there is a national lag in the application of new scientific data to every-day problems. We as a people are so wonderfully keen in developing mechanical ideas when once they are presented, that the marked lag in the acceptance and application of chemical principles is remarkable.

The industries themselves are frequently to blame for disappointing results which sometimes are met in an attempt to introduce scientific methods into their works. They employ a so-called chemist, without inquiry as to whether he has had the kind of training that could be expected to fit him for the work he is expected to do. They furnish him with a meagre equipment and then expect revolutionary results. When these are not forthcoming they exclaim in disgust: "There is no money in chemical control, or chemical research, we have tried it."

But there are signs of a change. The most distinct one is the impatience shown by some of the more enterprising manufacturing concerns, to wait for scientific facts to be discovered by others, and their willingness to establish research laboratories within their own organizations; to actively enter the field of research in applied chemistry.

How does research in "applied chemistry" differ from research in "pure chemistry"? Dr. Walker made the distinction clear by an analogy. The development of research in a science may be compared to the exploration of a new country. New roads are to be laid out, tunnels bored and bridges built, in other words, new problems solved. This may be done in two ways. First, constructive work may be undertaken wherever an interesting problem presents itself, without regard as to whether there is a demand for such structure or not. As a rule, the builder is under no great pressure to get the structure com-

pleted. This may represent the method of pure chemistry, and the great advance in chemical knowledge of the past was made almost entirely by boring just such tunnels and building just such bridges. The industries have used these structures when they could, or when some second builder could adapt them to use.

Research in applied chemistry differs from that just described only in this or it needs differ only in this, that when a problem is to be solved, a bridge to be built, the work is undertaken at a point where there is a demand for its use; where people are waiting to cross over so soon as it is finished. The method of building is no different, the difficulties no less. The fact that the bridge is to be used makes the work of the building no less dignified, nor is it possessed of less pleasure.

Why is there not the respect for this kind of work as when a bridge is built with the knowledge that it may not be used for an indefinite period? Why does an eminent writer a few months ago lament the fact that there is not more research "uncontaminated with the worship of usefulness"? Why does usefulness contaminate? Dr. Walker thinks it lies in this. The investigator of pure science works in the broad daylight, throws his product open for inspection, and invites all to come and use it when they can. In applied chemical research the spirit of the alchemist tends to creep in. The builder keeps his materials of construction and his designs a secret, and so boards up his bridge that those who cross over it cannot see how it is built, nor profit by his experience. The moment a thing becomes useful we become jealous of its possession; we become narrow in our horizon; we sell our scientific birthright for a mess of pottage; we become alchemists.

There is a heavy moral obligation on the part of large industrial organizations having fully equipped research laboratories to contribute their share to the advance of the world's knowledge. An obligation to see to it that they do not become saturated with the spirit of alchemy. They have well-stocked libraries and are provided with all the current periodicals; they profit by all the scientific work which has been done and is being done. This is as it should be, and such firms are to be commended for their progressiveness. But is there not a reason why such laboratories should do their part in adding to the sum of available knowledge? There is in every laboratory much work which could be published while the interests of the corporation are conserved.

Germany is very justly held up as a shining example of marvelous industrial progress and prosperity. A very great deal of the credit for her present position is due to her splendid educational system. But no small factor in her national progress is the helpful attitude which her industrial organizations take toward the publicity of scientific data. The individual does not suffer, while Germany both from a scientific and an industrial standpoint is rapidly advanced.

But too often with us the president and his board of directors are alchemists; they fail to see why if they pay the salaries of the research men, they should give the public or their competitors any part of their results. They exclaim "what has posterity done for us"? They would have their laboratories remain the secret chambers of the alchemists, and continue to improve their methods of changing baser materials into gold, without regard to the obligations which they owe their fellows.

It is to the men who form the working force in our industrial laboratories that we must in a great measure look for making our national scientific societies the power for industrial progress which they ought to be. But it is this general disinclination on the part of industrial concerns to allow their chemists to disclose in any measure the results of their work by contributing papers for the meetings or in entering heartily into the discussions that makes this realization difficult.

This is to be deeply lamented and we believe it is the fundamental mistake; a short-sighted policy which can but react upon industrial progress as a whole. We cannot operate a scientific laboratory as we would do a factory. The conditions of maximum productiveness are not found in an atmosphere of selfish rivalry.

It requires no extensive mathematical calculation to prove that the manufacturers themselves would be the ones to profit by more liberal treatment of the results of scientific work.

Of one hundred manufacturing concerns each one would give but 1 per cent of the whole contribution, while he would receive the remaining 99 per cent. He could not in the long run be the loser. But of vastly more importance he would feel and know that his organization was taking part in a world movement toward that increase of human knowledge upon which all real progress depends. The greater sense of satisfaction, the greater success even of an industrial organization lies in a fuller, freer, more generous publicity of the scientific results of their laboratories.

Would that we might benefit by the experience of Solomon, King of Israel, when asked "What shall I give unto thee?" replied "Give me knowledge and wisdom," and he answered, "Wisdom and knowledge are granted unto thee, and I will give thee riches and wealth and honor."

Surface Action and Electrochemistry.

Dr. Harrison E. Patten, of the Bureau of Soils, U. S. Department of Agriculture, Washington, D. C., then lectured on the subject of the relation of surface action to electrochemistry. In a brief introduction he outlined the general form of treatment as follows: First, a definition of surface tension as the first derivative of surface energy with respect to surface change; second, a consideration of the general equations of surface changes following the treatment given by J. Willard Gibbs; third, an extension of these equations with the assistance of a cyclic process to surfaces having an electric charge; fourth, the application of the general equation developed in the third section to electrocapillary phenomena, to migration of suspended particles, and to electric osmose; fifth, the relation of absorption phenomena to electrocapillary phenomena, to settling of suspensions, to formation of deposits, and to the behavior of disperse systems in general.

The lecture was illustrated with slides, so that a concise survey of the numerous mathematical and physical factors entering in was given in a short space of time. The lecture will be printed in full in the Transactions.

Electric Iron and Steel Furnaces.

At the Saturday morning session two papers on the electrometallurgy of iron and steel, previously presented before the Chicago section of the society, were called up for discussion. The first was a paper by Mr. James Lyman on "The Electric Furnace for the Manufacture of Iron and Steel," describing the Frick electric reduction arc furnace for smelting iron ore, the Frick induction type furnace for refining iron and steel, the Heroult furnace, and induction electric furnaces.

Electric Steel Refining at South Chicago.

The next paper by Mr. C. G. Osborne, of the Illinois Steel Company, of South Chicago, Ill., gave an account of a few experiences with the 15-ton Heroult electric furnace at South Chicago at the Illinois Steel Company's works of the U. S. Steel Corporation.

The paper first gives a description of the furnace. This particular furnace was described and illustrated in some detail in our Vol. VIII, page 179. Further details are here given from Mr. Osborne's paper.

The furnace shell is of plate steel, 1 in. (2.5 cm.) in thickness, riveted together. The outside horizontal cross-section plan is approximately that of a complete circle of 13½ ft. (4 meters) in diameter, with two flattened portions situated at the front and back respectively.

On the bottom of the furnace, within the 1-in. plate, and next to it, one row of magnesite brick, laid the 4½ in. (11.5 cm.) way, is placed across the flat portion.

The side walls of the furnace are vertical and consist of two rows of magnesite brick, laid the 9-in. (22.5 cm.) way, giving

a thickness of 18 in. (45 cm.) of magnesite brick. These solid magnesite brick walls extend up to the furnace roof.

The bottom "proper" of the furnace consists of dead-burned Spaeter magnesite to a depth of 12 in. (30 cm.) at its thinnest point, which is, of course, at the extreme center. From this thinnest point the bottom slopes gradually upward so as to form a portion of a sphere 7 ft. 2 in. (2.15 meters) in radius.

This bottom was put in in the following manner: Dead-burned and carefully ground Spaeter magnesite was mixed with basic open-hearth slag in the proportion of four of magnesite to one of open-hearth slag. To this mixture, sufficient tar was added to make the mass sufficiently plastic to enable it to be tamped into the furnace in the usual manner. The entire depth of the bottom was tamped in this way. Next, the furnace was filled with wood, dried out for about 48 hours, and then filled with coke, and the electrodes lowered and the current turned on. In this way the bottom was fluxed into place.

The furnace roof is of silica brick 12 in. (30 cm.) in thickness.

The roof is made up on a movable ring. This ring is fitted with a top and bottom angle iron to take a skew-back brick, and then from this the arch is spanned across the 10-ft. (3 meters) interior of the furnace with an 8-in. (20 cm.) rise. The bricks are set in circles parallel to the steel ring, the usual wooden wedges being placed here and there to take care of the subsequent expansion of the brick. Holes for the electrodes are left in the roof by means of templates placed in position. The bricks are held in position around these holes by their lateral pressure.

There are five doors, two on each side of the furnace, and one in front over the pouring spout. These doors are of cast iron, lined with clay brick, laid the 4½-in. (11.5 cm.) way. They work in the usual groove arrangement, and are operated by steam pressure of about 150 pounds (11 kg. per sq. cm.). The front door over the pouring spout is an exception to this, being operated by hand with a counter balance.

The three electrodes are let down through the roof in the form of an equilateral triangle, each side of which is 5 ft. 2 in. (1.55 meters) in length, the apex of this triangle pointing directly east, that is, toward the back of the furnace. The center of this triangle coincides with the center of the furnace roof.

There are, of course, three separate holders, one for each electrode. Each holder is constructed of a solid copper casting bolted directly to the bus-bar. In front, these holders are split and joined with a right and left screw, which enables the holder to be opened or closed at will. The holders are designed to carry a 24-in. (60 cm.) electrode, but by means of contact blocks to fill, any smaller-sized electrode can be employed.

The weight of the electrode is supported by the chains. These chains run back over pulleys to the drums at the back of the furnace. These electrodes are kept in alignment by vertical guides.

The electrodes are regulated by individual motors placed at the back of the furnace. These motors are attached by gears to the drums. The regulation is by hand, by controllers, or by an automatic device.

The operating platfrom of the furnace is about 9 ft. (2.7 m.) from the level ground. Around the furnace on this platform, at convenient points, bins are placed for the miscellaneous materials used in furnace operation.

The front part of the furnace platfrom opens up to allow a ladle to be hung in position when the furnace is tapped and for any miscellaneous work in the pit.

The power for the furnace is generated by dynamos having as prime movers reciprocating gas engines, reciprocating steam engines, high-pressure and low-pressure turbines. It is three-phase, 2200 volts and 25 cycle.

At the electric furnace it is stepped down by means of three 750-kw transformers to the voltage of the furnace. These transformers are so arranged with switches that the primary turns may be altered to give a secondary voltage of 80, 90, 100 110 volts as desired. Ordinarily 90 volts is used.

The entire building is spanned by a 50-ton crane.

The pouring platfrom is situated to the south of the furnace. It is 30 ft. (9 meters) long, and enables eight molds to be placed in position for pouring.

The normal operation of the furnace is as follows:

Ordinary Bessemer pig iron is full blown in a 15-ton Bessemer converter, in from eight to twelve minutes. It is then poured directly from the Bessemer vessel to an electric furnace transfer ladle, and drawn by locomotive to the electric furnace building, a distance of about ¼ mile (400 meters), in about five minutes. As a precaution against the possible formation of a skull in the ladle, the Bessemer charge is blown about 1500 lb. (680 kg) of scrap "hotter" than ordinary Bessemer practice.

Immediately the ladle is received at the electric furnace it is picked up by the crane, slightly tilted, and the silicious slag is completely cleaned off by hand-rabbling. The metal is now ready for charging. To do this, the ladle is merely turned over on its trunions and the metal poured into a spout, through which it rushes to the furnace. This operation of cleaning off the slag and charging occupies from five to ten minutes.

The electrodes are lowered and the current turned on.

As the metal is being poured into the furnace, the helpers shovel iron oxide and lime into the furnace through the working doors.

In this way a basic oxidizing slag is produced which serves to remove the phosphorus. In about thirty minutes this slag has served its purpose, and the furnace is tilted slightly forward and the slag removed in from five to ten minutes by hand-rabbling.

The recarburizer is added at this point. On the bare surface of the oxidized metal, lime is quickly added, with sufficient fluor-spar to keep the mass fluid. In about fifteen minutes this lime is melted, and finely divided coke dust is now thrown onto the top of the slag beneath each of the three electrodes.

Under the influence of the arc, calcium carbide is produced in gradually increasing quantities.

As soon as this state of affairs is reached, a neutral if not actually reducing atmosphere has been obtained. From here to the finish there is practically a dead-melt in a reducing atmosphere. The slag at this stage of the process is fluid and highly basic. If a sample should be taken and water added to it, the resultant acetylene gas, from the well-known calcium carbide and water reaction, is of sufficient quantity to light and burn for half a minute.

Tests are now taken to show the condition of the steel. A small cylindrical test piece is poured and forged to a round pancake-shaped object under a steam hammer located at the furnace. If this forged sample shows by its appearance a satisfactory condition of the metal, the bath is tapped. If not, further refining is necessary.

To tap the furnace the electrodes are raised from the bath and the ladle swung by a crane under the pouring spout and the tilting level pulled forward.

The pouring is done through a 1½-in. (4-cm) nozzle to molds of varying sizes.

It takes an hour and a half to two hours to a heat, according to the grade of steel produced.

What is actually done in the electric furnace at the South works is to take oxidized blown metal of an approximate analysis of

C	S	P	Mn	Si
0.05-0.10	0.035-0.070	0.095	0.05-0.10	0.005-0.015

and produce deoxidized steel low in sulphur and phosphorus and, within reasonable limits, of practically any analysis required by the consumer.

The electric furnace at South Chicago has operated on a greater variety of product than any furnace in the world, and with bewildering intermingling of high-grade alloy steels, high-grade carbon steels and ordinary carbon steel. They have made

ordinary carbon steel rails of a dozen different sections, billets of all sizes and grades, plates of all sizes and grades, structural shapes, castings, small and large, high carbon and low, and forgings of all sizes; of alloy steels they have made nickel, nickel-chrome, chrome, manganese and silicon steels.

They have made a number of heats from cold materials. In several of these they took the worst scrap they could pick up—stove-plate scrap. With this stock an axle heat was made which showed excellent physical tests. Seventy-seven blows from a 1640-lb. (750-kg) hammer falling 43 ft. (13 m) broke the first axle, and 68 similar blows the second.

The main chemical or physical characteristics in electric steel seem to be these:

A comparative freedom from oxidation.

A comparative freedom from segregation.

A higher tensile strength and slightly higher ductility for the same chemical analysis up to about 0.40 carbon, where the difference becomes less apparent.

A steel of greater density than other commercial steels, with the possible exception of crucible.

In conclusion, Mr. Osborne said that the three electric furnaces of the Steel Corporation are the largest in the world that have as yet been put in operation. They have presented many interesting and complex problems, and the manufacturer has encountered occasional troubles. "Although we feel that we are as yet but on the threshold of this method of manufacture, we feel that electric steel is a success and its future assured."

Mr. Osborne's paper brought out considerable discusion. Mr. Osborne stated that the South Chicago furnace was the oldest of the Héroult electric furnaces of the Steel Corporation and that in the newer one in Worcester several improvements have been made, especially in the arrangement of the electrodes. While it takes five minutes in Worcester to change electrodes, it takes half an hour in South Chicago. Other disadvantages at the South Chicago plant are the relatively small space available and the distance of the electric furnace from the Bessemer converter house, which makes it necessary to blow the steel 200° or 300° hotter than ordinary Bessemer metal. This accounts for the fact that the metal comes colder out of the electric furnace than it goes in. They have used all kinds of electrodes; at present they are using 14-in. amorphous carbon electrodes of the National Carbon Company.

In reply to a question by Mr. Hansen, Mr. Osborne stated that the increased tensile strength of the electric steel is due to greater density. The greater density is due to absence of gases. Electric steel, properly made, has segregation practically nil, except right below the pipe.

Mr. Saunders considered it the function of the electric furnace to do only the most difficult work, to supply only the peak of the temperature, and referred to a furnace of the National Carbon Company, which is chiefly heated by gas and only the last 200° or 300° are supplied by electricity.

Mr. Hansen disagreed with respect to the use of electric furnace for peak work only; he considered this as uneconomical, since the overhead charges of the electric plant go on all the time.

Dr. Richards referred to the use of the electric furnace as a dead melter without any refining. Simply by holding the finished steel in an electric furnace, say, for 30 minutes, to let it rest and let the oxides and gases rise and get out, it is possible to improve the quality of the steel considerably.

As in the South Chicago practice the steel goes hotter into the electric furnace than it comes out of it for the local reasons stated above it is evident that the advantage of the electric furnace in this case is not thermal efficiency. This brought up again a discussion on the efficiency of electric furnaces.

Dr. Richards argued that two kinds of efficiency must be distinguished. First, there is the case where the furnace is used as a melting furnace; electricity is then used to raise the temperature. Second, there is the case where the metal is simply kept molten at a materially constant temperature; in this case the efficiency must be defined differently from the first case. Both cases must be clearly distinguished.

Mr. Langmuir thought that in the second case it was hardly possible to speak of efficiency because the use of this term presupposes that a 100 per cent efficiency is imaginable.

Dr. Lidbury expressed the opinion that there was nothing to be gained at all by speaking of the "thermal efficiency" of an electric furnace, because in order to express it in percents it is necessary to make so many arbitrary assumptions and hypotheses on account of a great many factors which cannot be measured. Instead of speaking of efficiency he preferred a straight statement that so and so many kw-hours are required per ton of metal produced, etc., as such specific statements would give all the information needed.

Dr. Richards thought that the use of the term "efficiency" was proper even in the case where it is simply a question of keeping a furnace charge continually at the same temperature, because one furnace does that with 50 kw per ton of charge and another with 200 kw.

Dr. Lidbury thought that such comparative specific statements as the one just mentioned gave all the needed information without bringing in "efficiency" at all.

Mr. Osborne stated that it was a matter of experience that with 14 practically identical open-hearth furnaces, as at South Chicago, the pounds of coal per ton of output might vary considerably, and that the figure depended essentially on the management. Hence the "thermal efficiency" would be in practice largely a question of management, of the hustling of the attendants, etc.

Electrolytic Furnace Process for Production of Pure Metals.

Mr. John Woods Beckman, of Niagara Falls South, Canada, presented a paper in which he expressed the opinion that the fused electrolyte would be the electrolyte of the future. He referred to the production of aluminium from alumina and asked whether it should not be possible to produce all metals in a similar manner from their oxides; but what electrolyte is to be used?

A comparatively little known group of salts are those occasionally occuring in nature, composed of equivalent amounts of calcium oxide and the oxide of any metal less positive than calcium. These salts occur occasionally in nature comparatively pure, as is the case with Scheelite, and can very readily be produced by heating the oxides together in any suitable manner.

There is a great number of these salts possible, and the characteristic feature of them is that they all fuse at about and over 1000° C., the temperature varying according to the metal oxide which calcium oxide is combined with. The boiling point of these salts is very high.

The valuable feature of these salts is that when in a molten condition they carry the current very readily, and are very suitable as molten electrolytes for the production of a great number of metals.

Mr. Beckman stated that he had produced in this way manganese, iron, chromium, and a 50 per cent alloy of vanadium.

To describe the principle of the process Mr. Beckman described the production of iron. Equivalent amounts of Fe_2O_3 and CaO are mixed together and heated in any suitable manner. The salt $CaO.Fe_2O_3$ is formed and fused in a receptacle fitted for electrolytic purposes. Oxide of iron is introduced into this fused bath, and this molten solution is electrolyzed, iron being deposited on the cathode and a lively oxygen development taking place on the anode.

If the electrolyte itself is submitted to the direct current, no noticeable reaction takes place, but the moment iron oxide is added the electrolysis starts, and by adding from time to time more oxide it can be carried on continuously.

The practical features of this method are: First, cost of electrolyte practically negligible, as it is composed of calcium oxide and the metal oxide of the desired metal; second, a great quantity of metal can be produced out of the same electrolyte;

third, in case the electrolyte becomes fouled the loss in discarding the electrolyte is practically negligible; fourth, the flexibility of the process making it possible to produce a great number of metals and their alloys, such as iron, manganese, chromium, zinc, tin, titanium, vanadium, tungsten, tantalum, molybdenum, nickel, cobalt, lead and a number of others more or less rare.

Mr. Beckman finally gave the following list of the theoretical amount of meal deposited per ampere hour, considering only ideal conditions:

	Oxide	Gram per amp. hr.
Aluminium	Al_2O_3	0.3377
Lead	PbO	3.868
Chromium	Cr_2O_3	0.655
Iron	Fe_2O_3	0.696
Manganese	MnO	1.027
Nickel	Ni_2O_3	0.732
Zinc	ZnO	1.220
Titanium	TiO_2	0.445
Vanadium	V_2O_3	0.64

There was considerable discussion of the paper, in which Messrs. Hansen, Bleecker, Tucker, Walker, Richards and Saunders participated. Mr. Hansen and Professor Tucker expressed the opinion that there was no experimental evidence that the metals produced by Mr. Beckman were the result of electrolysis, since on the small scale employed there might have been simple high-temperature reduction by carbon from the graphite crucible.

An Electric Converter Process.

Mr. ALBERT E. GREENE, of the American Electric Smelting & Engineering Company of Chicago, presented a paper on "Electric Steel Processes as Competitors of the Bessemer and the Open Hearth." This is a new development, as heretofore electric steel processes have been used largely for the production of high-grade steel, practically of crucible-steel quality. Mr. Greene urges, however, that there is a distinct possibility

FIG. 1.—ELECTRIC CONVERTER.

for an electric-furnace process for ordinary grades of steel in competition with converter and open-hearth on account of the unavoidable great losses of metal in the two latter processes.
